ORIGINAL ARTICLES.

SPECIFIC THERAPY OF TUBERCULOSIS AND VACCINATION AGAINST THE DISEASE.*

BY PROF. EDOARDO MARAGLIANO,

OF GENOA, ITALY;

PROFESSOR IN ORDINARY TO THE ROYAL UNIVERSITY OF GENOA: DIRECTOR OF THE MEDICAL CLINIC, AND OF THE INSTITUTE FOR THE STUDY AND THE CURE OF TUBERCULOSIS AND OF OTHER INFECTIOUS DISEASES IN GENOA.

I.

GENTLEMEN: Honored by your invitation I have accepted it with enthusiasm because it gives me much pleasure to speak in this great country of my studies in tuberculosis.

I come before you, a body of distinguished men, who have no fear of the new ideas that have broken the chain of old scholastic tradition in every field of human knowledge, and who bow down without reserve before the facts not caring whether or not they conform to prevailing doctrine. I shall speak to you with much confidence, because I am certain of receiving your approval.

The studies of which I am going to speak are both clinical and experimental.

I have lived for thirty-four years in public clinics and scientific laboratories, and for more than twenty years I have been the director of a great university clinic, in which tuberculosis always has been the object of my studies. I therefore have had the opportunity of acquiring a very large experience in tuberculous diseases; I have always held, however, that all clinical observation ought to be combined with assiduous laboratory research in order to illustrate and investigate the vast problems presented by tuberculosis. I accordingly established a special laboratory for the study of tuberculosis in my clinic, and afterwards founded an Institute for the study of the same. In this Institute, open to the students of every nation, a host of workers carry on experimental research under my direction. It would have been impossible without great means and a large number of able coworkers to have accomplished so much work. I might mention among these collaborators Lucatello, Marzagalli, Jemma, Mircoli, Sciallero, and Figari.

It is my conviction, moreover, that it is only by the association of clinical and laboratory work that it will be possible to solve the great problem of tuberculosis. Laboratory research alone does not accomplish the end, but it will never retard its development.

In my studies I have been inspired by two fundamental conceptions only, one relating to the cure of tuberculosis, the other to its prophylaxis. In regard to the cure, my desire has been to find out whether a specific defensive medium against tuberculous infection exists in the animal organism, or can be produced in it, and whether it is possible to utilize it for curative purposes. With reference to prophylaxis, the question was, whether or not it is possible to develop in the healthy animal organism, as is done in other infections, a special specific activity which will immunize the patient against tuberculous infection for a greater or less time.

All my researches on the question, both clinical and experimental, for more than fifteen years lead me to state: (1) *That it is possible to produce a specific therapy for tuberculosis;* (2) *that it is possible to immunize the animal organism against tuberculosis as is done in other infectious diseases, and that there is good reason to hope for an antituberculous vaccination for man.*

II.

I will now tell you at the start on what data and facts I have based my right to make these statements.

In order that I may be better understood, it is necessary for me first to set down a few fundamental ideas on the pathogenesis and pathology of tuberculosis, the result of a series of researches carried on by myself and my colleagues.

First of all I will say that the changes caused by tuberculous infection, in the tissue of an organism, and in the organism in general, are due to the poisons secreted by the bacilli when they are biologically active, and to the poisons contained in the bodies of the bacilli.

We have extracted those secretions of the bacilli known as the toxins by means of filtrations of the young cultures. We have found that they had a disturbing action upon the nervous system, especially upon that part governing the secretory mechanism and upon the nerve terminals as shown by profuse perspiration and great depression of temperature. Those contained in the bodies of the bacilli, known as proteins we have extracted with water in which they were more soluble than in any other menstruum. These have an inflammatory and destructive action on the tissues with which they come in contact, due to the necrotic acid of de Schweinitz and Dorset, and have therefore a disturbing action on the vasomotor innervation, on the trophic nerves and their terminal centers creating considerable elevation of temperature.

These poisons, extracted from the bodies of the bacilli, are the most pernicious. Injected beneath the skin they cause inflammation with purulent, fibrinous exudation, and bring about necrosis of the tissues; injected into the lungs they create foci of bronchopneumonia; when brought into con-

*A lecture delivered before the Henry Phipps Institute in Philadelphia, March 28, 1904.

tact with the meninges and peritoneum they set up inflammation. The bony tissues are also affected, presenting changes that remind one of rachitis.

In connection with these phenomena, many of which have already been seen and confirmed by other observers, it is very necessary to recognize the fact that the bacilli cause their pathogenic action in the animal organism by means of this double series of poisons, of which the proteins are the most powerful. The bacilli are of moment in that they produce these poisons and by multiplying also increase the poisons. The proteins favor their diffusion because by impoverishing the nutrition of the tissues they create a favorable soil for the productiveness of the bacilli. If one thigh of a guinea-pig be injected with bacilli and protein together, and the other thigh with bacilli alone, it will be seen that the infection travels much more rapidly on the side in which the bacilli are injected with the protein.

Another truth first proclaimed by us, and since confirmed by many other observers, is the fact that there are minor influences bearing upon the development of tuberculosis, the most noteworthy being that of the common pyogenic organisms, which favor the destruction of tissue invaded by tuberculosis and set up severe toxemic conditions.

From these new ideas light is shed upon the pathogenesis of tuberculosis. When the bacilli grow in a tissue they create there, by means of their poisons, a specific circumscribed inflammation, and form characteristic neoplasms, viz., tubercles. The nutritive changes then favor the growth of new bacilli, and thus new foci are formed progressively, and the changes in the tissue gradually become greater. If common pyogenic organisms chance to get into this tissue from the outer air (as may easily happen in the lungs) the destructive processes are aggravated and progress more rapidly.

From the bacterial foci the poisons pass into the general circulation, and set up phenomena of toxemia, which manifest fever, sweats and loss of weight. We have proof of this toxemia, because we have been able to demonstrate the presence of bacterial toxins in the urine and blood of persons having the disease.

After having gained a clear idea of the method by which tuberculous infection is developed we have turned our investigations to the discovery of the method by which the animal organism defends itself against it.

Our researches have shown that in the animal organism the elements of the tissues and the fluids possess a special defensive activity.

If we inject under the skin of such animals as the rabbit, dog, ass, horse or cow a small measured quantity of tubercle bacilli, and watch the daily changes in those bacilli, we see that little by little alterations take place in their vitality and that they are finally destroyed altogether.

If we inject directly into the lungs of a healthy animal the smallest measured quantity of tubercle bacilli we find that the bacilli undergo change and destruction without creating any lesion.

This defensive action of the tissues may not be in evidence when the number of bacilli injected is large; but it is manifest when they are few in number.

The serum of the blood of man and of other animals when in health also produces a decided effect upon tubercle bacilli.

We have studied methodically the culture of tubercle bacilli in the sera of different animals, deducing the inhibitive power of the serum by the facility with which the cultures develop in various degrees of dilution of the culture broth. It is evident that the higher the degree of dilution in which the serum exercises its action upon the development of the bacteria, the greater is its richness in antibacterial bodies.

The animals which we have studied are man, the horse, the cow, the calf, the dog, the hog, the rabbit and the guinea-pig in a condition of health.

The sera have been found to stand in this order of potency: the calf, the cow, the hog, man, the horse, the dog, the rabbit, the guinea pig. Those of the calf, the cow, the hog, man, the horse and the dog differ but slightly from one another in potency, while at a great distance from these stand those of the rabbit and guinea-pig, especially the latter, which has no action at all upon the development of the tubercle bacilli, for in its serum the bacillus develops just as well as in a common culture medium.

The serum of healthy animals, therefore, has in a definite but limited degree a defensive action against tuberculous poisons.

These defensive powers can be measured exactly by my method.

This method consists in determining by a series of graded experiments, what quantity of serum is necessary to save a guinea-pig from a mortal dose of *text-gift*. This test poison is a liquid which contains the product of tubercle bacilli macerated with heat in water, the dosage being fixed upon the basis that one cubic centimeter of the solution subcutaneously will kill a hectogram of a healthy guinea-pig.

By this method we have tested the blood of man, of the cow, the calf, the goat, the horse, the turkey-cock, the rabbit and the guinea-pig in good health.

The blood serum of the rabbit and of the guinea pig has no antitoxic power whatever, nor do the sera of other animals furnish a very great quantity. The richest in antitoxic materials is the serum of a healthy man. Then comes that of the turkey-cock, the calf, the cow, the goat and the horse.

The study of the power of agglutination carried on according to the method of Courmont-Arloing, on homogeneous cultures gives almost analogous results; none in the guinea-pig, almost none in the rabbit, sometimes an appreciable amount in other animals, especially in a strong, healthy man.

This triple power of the blood serum, bacteri-

cidal, antitoxic and agglutinating, increases considerably if a healthy animal is injected with tuberculous matter.

The bacillary poisons, the bodies of dead bacilli and living bacilli, introduced into the body of a healthy animal, produce in it antitoxins and antibodies and give it a special antitoxic, bactericidal and agglutinating property, while on the other hand they increase in it the destructive power of the tubercle bacilli in the tissue. With the methods of measuring and examining which I have invented, and of which I have already spoken, these facts may be proved exactly, and by the same methods which I have used any one who wishes to verify them for his own satisfaction may do so.

The production in healthy animals of agents of defense in the presence of tuberculous material was discovered before me by other observers in Europe, as well as in America, and among others by de Schweinitz and by Trudeau.

I took up the study of this question in 1890 in a methodical progressive manner, and I have been able to show with exactness the presence and amount of tuberculous antitoxins in the blood of animals that were under suitable treatment. I announced the fact in Bordeaux in 1895.

I use the word antitoxins in a broad sense, meaning by this name to designate all those defensive materials, taken together, which Büchner very appropriately called "Schutzkörper."

The existence of this antitoxin, at first denied, is to-day universally recognized, and constitutes as we shall see shortly the foundation for the specific therapy of tuberculosis.

The consecutive studies carried on in my school have led me step by step to prove the existence of antibodies and agglutinating substances and have enabled me to establish now, after many years' work, the doctrine of the defense of the animal organism against tuberculosis.

The healthy animal organism possesses a double series of defensive measures against tuberculosis, which may be called ordinary means of defense, and extraordinary. The ordinary means are naturally inherent in the tissues and secretions of the animal in a perfectly healthy condition, and are partly antitoxic and partly bactericidal. The extraordinary means are also antitoxic and bactericidal and develop principally in the presence of the tubercle bacilli that penetrate the tissues.

The cellular elements of the organism manufacture, as it were, substances which react against the invading bacteria and destroy and neutralize their poisons. If the organism produces defensive means in proportion to the number of invading bacteria it gains the victory. If, on the other hand, the defensive means are not sufficient, the bacteria gain ground and the organism succumbs. This happens when the bacteria growing on a tissue are very numerous, or, when not numerous, the organism is in a weak condition.

The proof of my statements may be found in the study of persons who have spontaneously recovered from tuberculosis as well as of those who have not recovered from it. In the former we find antitoxin and antibodies in large quantities in the blood; in the latter we do not find them, or only in small quantities.

Thus the vulnerability of an animal exposed to tuberculosis depends on the number of bacilli by which it is attacked and upon its reactive powers.

For this reason animals in a weakened condition are able to defend themselves if the number of invaders is small, and those that are more able to resist will succumb if the number of invading bacteria is large.

III.

These facts, gentlemen, brought up the question whether it would be possible to furnish those specific means of defense to the organism struggling against tuberculosis which are produced only a little at a time or in insufficient quantities.

Inasmuch as healthy animals inoculated with tuberculous matter produce the materials of defense found in their serum, it was but natural to seek to know whether the serum of these animals containing antitoxins and antibodies could be used as an aid to an organism struggling against tuberculosis.

From this was born, by a logical association of ideas, the suggestion of antituberculous serum therapy.

The serumtherapy which had been tried in America by de Schweintz, by Trudeau, by Stubbert and others was subjected by me to the severest scientific tests, such as are used for the serumtherapy of diphtheria and other infectious diseases.

But I would add, that it was done upon a much broader and larger basis, because in diphtheria the question was not studied as I have studied it analytically in tuberculosis, and because in diphtheria the natural defensive process of the organism was not demonstrated as I have demonstrated it against tuberculosis.

I will not trouble you with the details of the laborious course I pursued in this new phase of my studies. I will only give that which is necessary to explain my conclusions.

First of all I have established by a series of experiments what is the best method of obtaining in the healthy animal a serum rich in defensive materials which at the same time can be used in man without suspicion of danger. I have at the present time discarded the injections of living bacilli, and after numerous trials I have selected as most suitable for inoculation an aqueous extract of virulent bacilli, but dead, supplemented by the filtrate of a young culture. In this way I get the full value of the bacillary bodies and toxins.

The animals selected by me for the production of this serum were the horse, the cow, the ass, the calf, the goat, the sheep and the dog. I am convinced that the horse, the cow and the calf are to be preferred. The richness of the serum in

antitoxic materials was determined by us in the guinea-pig by means of the *text-gift*.

Our *text-gift* consists, as we have already said, of an aqueous extract of the bodies of the bacilli in an exact dosage; that is to say, so that one cubic centimeter of it would kill a healthy guinea-pig weighing a hundred grams. The potency of the serum is determined by the quantity required to save a healthy guinea-pig from a dose of the *text-gift* that has been established as deadly.

The standard of potency of the serum is established by the quantity which succeeds in saving a healthy guinea-pig of a certain weight from a deadly dose of *text-gift*.

The relative weight of the serum used to the weight of the animal saved, establishes the power of the serum. The antitoxic unit is established by a gram of serum capable of saving a gram of healthy guinea-pig. That is to say, a serum of which one gram will save a healthy guinea-pig weighing a hundred grams possesses one hundred antitoxic units, and it would need to possess one thousand units in order to be able to save a healthy guinea-pig weighing a kilogram, and so on.

The antibacterial materials, known as antibodies, have been studied by us in several ways. First we have added the serum in various amounts to a culture of tubercle bacilli, as we have already indicated, and thus have found how much it takes to prevent development. Next we have kept virulent bacilli immersed in the serum so that we might see whether they could still be cultivated, and were capable of giving tuberculosis to animals upon inoculation. Then we have injected virulent bacilli combined with the serum, and have seen to what degree they would render the guinea-pig and rabbit tuberculous.

The measure of the agglutinating power completes this research, and gives us the method of measuring the antibodies which are in the serum.

When the horse, the cow or the calf, under proper treatment, attains the power of giving a serum which has *at least* a thousand antitoxic units per cubic centimeter, and shows upon every test a bactericidal power, and which has reached an agglutinating power of at least one to three hundred, such serum may be used for therapeutic purposes, because it contains a sufficient quantity of antitoxin and antibodies.

When in Bordeaux in 1895 I said it was possible to obtain a serum rich in defensive antituberculous substances, chiefly antitoxin, everyone doubted it. To-day, all the laboratories, beginning with those of Behring and Koch, admit that it is possible to have a serum with specific antitoxic substances and specific antibodies.

The richness in antitoxic substances or in antibodies varies according to the method of treating the producing animal. If the animal is treated simply with toxins it is rich in antitoxin, and poor in antibodies. If it is treated with the bodies of dead bacilli, or an extract of the same, it is rich in antibodies, and poor in antitoxins. Recently we have succeeded in producing sera with an agglutinating power of 1-2,000 and even more, which have in addition a thousand antitoxic units to the cubic centimeter. I have tried to determine whether this serum would be innocuous to tuberculous animals and tuberculous men by injections into healthy animals and men. I am convinced that it is innocuous.

I have wished to see what would happen in the organism of healthy animals and healthy human beings into whom this serum has been injected. I have found by means of my method of grading the dose that with its use there has been a marked increase in the quantity of antituberculous substances which are found in the circulation.

Inasmuch as I found that according to this method of measuring the antitoxic and antibacterial powers of sera, there was an increase of defensive substances in the blood of the injected animals greater than the geometrical proportion I am obliged to conclude that the organism plays an active part in this tremendous increase. And inasmuch also upon the injection of the same serum in subjects that were very sick this increase did not take place, I am convinced that the participation of the organism is necessary to this increase.

I have wished, in short, to see what would happen in the organism of a tuberculous man in whom this serum was injected, and I have found the following: If there were no defensive substances in the blood before its use they appeared afterward. If, however, they had been there before, they were markedly increased afterward. I saw also that by means of its use toxic symptoms disappeared or were diminished. The progress of local inflammation was modified and caused to disappear.

In consequence of this action we observe in a general way diminution and disappearance of fever; diminution and disappearance of sweats; progressive improvement of the nutrition resulting in considerable increase in body weight.

And then, from a local point of view: The disappearance of the foci of bronchopneumonia, the production of foci of connective tissue, so as to form a sclerosis at those points which are involved by the disease; diminution and disappearance of the cough and expectoration; and finally, the disappearance of the bacilli, all of which are clinical signs of cure.

All these results *do not follow* in all cases of tuberculosis, but they do follow in nearly all cases of tuberculosis in the beginning of the disease. They do not follow when the general nutrition is profoundly impaired; they do not follow when there are centers of mixed infection with extensive destruction of tissue. They do not follow, in short, when tuberculosis has become phthisis.

I hold strongly to this differentiation between tuberculosis and phthisis, meaning by phthisis that morbid state in which the lungs by the combined action of tuberculous infection and pyogenic infections are the seat of destructive lesions, while the organism as a whole is profoundly affected

in its nutrition by the result of combined toxemiæ; namely, tuberculous toxemia, streptococcus toxemia, staphylococcus toxemia and even others.

When I announced these therapeutic results in Bordeaux in 1895 they were received with doubt. So deeply rooted in medicine is the conviction of the incurability of tuberculosis that any announcement of a new method of treatment awakens incredulity. But the use of antituberculous serum therapy has become spread abroad. In Italy as well as in other countries the serum prepared by my method has been used in large quantities. In these nine years there have been at least 20,000 cases of tuberculosis treated by my method. Naturally it is impossible for me to have data of all these cases. I have only been able to collect the notes of 2,899 cases. These were collected in a statistical communication by one of my most valued coworkers, Prof. Mircoli, to the Congress of Tuberculosis in Naples. These statistics show that out of more than 250 cases of circumscribed non-febrile tuberculosis 38 per cent. were cured and 49 per cent. were much improved; that out of 938 cases of circumscribed febrile tuberculosis, 18 per cent. were cured and 54 per cent. were improved; that out of 665 cases of diffuse tuberculous bronchopneumonia without microbic associations 14 per cent. were cured and 43 per cent. were improved.

Out of 332 cases of diffuse tuberculous bronchopneumonia with associated microbic infection 9 per cent. were cured and 36 per cent. improved. Of 712 cases with cavities and lesions 6 per cent. were cured and 40 per cent. were improved. Of all these patients 2,396 were in a febrile condition. The fever disappeared in 1,111 cases, that is, in 46 per cent.

As regards my personal experience, I can say that I have seen the most assuring results, and that the cures have persisted in those patients whom I have been able to follow. I have some that have survived seven and even nine years. I have seen the best results in ambulatory patients, but I also have had pretty good results in inmates of my clinic. In the hospital only those invalids come for treatment who are in a bad condition, and who are not at all in the same class as the ambulatory patients, for they are phthisical as well as tuberculous.

In this connection, it must not be forgotten that if the serumtherapy is to succeed there must be cooperation in the organism of the sick person, and if this organism is not in condition to keep up active cooperation, the treatment will be futile.

In your country, also, antituberculous serumtherapy has shown remarkable results from what I have been able to gather from a communication made by Prof. de Schweinitz, of Washington, to the International Congress of Tuberculosis in Berlin.

I believe that if one asked of serumtherapy only what could reasonably be demanded of the therapy of any disease, confidence in it would increase, with great benefit to mankind. I say this because physicians demand in tuberculosis what they would not dare to ask for in other diseases, or of those remedies which are best known and surest in their action.

No physician, for example, pretends that a heart with myocardiac degeneration ought always to maintain its functions; and he does not lose faith in the efficiency of digitalis, if the digitalis does not succeed in restoring activity to such a heart. No physician pretends that a liver violently affected, severely impaired in its nutrition by malaria, should return to its normal state by means of quinine, nor does he lose faith in quinine when he does not succeed.

The same may be said of mercury when the tissues are already destroyed, or deeply affected in their nutrition by the effect of syphilis. Would one, perchance, lose faith in corrosive sublimate if he should not cure by means of it a case of tabes dorsalis of syphilitic origin?

In tuberculosis, however, everything is expected always and in every case. And, furthermore, a remedy is wanted, not only to combat tuberculosis, but to build up an organism already destroyed by tuberculous infection. These are the unreasonable claims that will never be satisfied by any remedy, and which until now have prevented physicians from properly appreciating the various proposed treatments for tuberculosis.

While on this point, permit me to put you on your guard against another error which is, unfortunately, widespread. It is this: Don't judge a treatment for human tuberculosis by experiments in the cure of guinea-pigs which have been given an artificial tuberculosis.

It will be seen as our knowledge concerning tuberculosis and serumtherapy increases that this hypothesis has been wrong.

It is wrong, because the tubercle bacillus develops different properties in the various organic soils, and above all in various animals; wrong because the serumtherapy is effective only through the active cooperation of the organism to which it is applied. Not only this, but there is also a great difference in the manner in which infection takes place between the guinea-pig and man, because in man we do not find the system struggling with such an enormous quantity of virulent bacilli injected at one time, as we do when a guinea-pig is artificially injected.

The efficacy of antituberculous treatment, therefore, should be judged exclusively by clinical observations, and I can now assure you with full conviction that clinical observation is very favorable to serumtherapy, and at the same time that serumtherapy has a broad and sure scientific basis, because it has been proved that the serum contains antitoxin; that the serum contains antibodies; that the introduction of the serum into the organism produces new antitoxins and new antibodies.

For the rest, serumtherapy does nothing more than reproduce the process followed by nature in spontaneous cure, adding its good effects to those of hygiene, given to the organism in sanatoria, because serumtherapy, hygiene, and sana-

toria all have the power of endowing the organism with the necessary energy to struggle successfully against tuberculosis.

I am convinced that in a few years, when physicians will have learned all the benefits that serumtherapy can give in tuberculosis, it will be remembered with regret that so many lives might have been saved, and were not, because physicians with preconceived doctrines put it aside, and gave preference to remedies which were sanctioned neither by science nor by practice.

IV.

In the beginning of my treatise I said that it was possible to immunize the animal organism against tuberculosis, as is done in the case of other infectious diseases. These results of my studies and experiments I announced at Bordeaux in 1895. At that time my statement seemed like heresy. To-day, on every side it is affirmed that it is possible to immunize animals against tuberculosis, so as to render them able to withstand, as I put it nine years ago, injection into the veins of a virulent culture of human tubercle bacilli. The methods used by me and by various other experimenters differ; the result, however, is the same, *viz.*, resistance to tuberculous infection.

Permit me now to leave all that which pertains to the historical side of the question, in order to enter at once upon the practical and essential part of the argument.

The positive proof that immunization has taken place consists in showing that the animal has become able to withstand the endovenous injections of a virulent culture of tubercle bacilli. But this proof should be kept within proper limits. Those who believe that they have proof of having attained immunization which will permit of endovenous injections of colossal unlimited quantities of a culture of living, virulent bacilli, are in error, because when a quantity of powerful bacilli has been injected, the animals frequently die quickly from severe toxemia, due to the poisons of the injected bacilli; they also err even when this does not happen, because the defensive means of the organism are not in proportion to the number of invading bacteria, and the animal becomes tuberculous.

The school of Koch likewise holds this view, and it is necessary to conform to it to avoid exaggerations which have made observers of the truth withdraw from us and which still keeps them at a distance.

It is necessary to have an exact standard, and it should be borne in mind that normally infection never occurs in man in the manner above described and with such violence; it also should be borne in mind that we ought to study the problem in its clinical aspects, and from the point of view of its applicability to bedside treatment. We should be satisfied with a limit, and the limit is indicated by the quantitiy of bacilli that is sufficient to develop in control animals a slowly progressive tuberculosis. If in immune animals this quantity becomes innocuous we should feel that we have attained our object.

It is important, therefore, to recognize and study the modifications which take place in the organism of animals just rendered immune in in this way.

This is what happens. Their tissues acquire the power of rapidly destroying the tubercle bacilli that have been thrown into them.

Thus by injecting virulent bacilli, according to the method which we have already given, under the skin of rabbits and asses that have been rendered immune, we find that the bacilli are destroyed more rapidly than in the tissues of the control animals that had not been immunized.

The blood serum of these animals acquires a special bactericidal property toward the bacilli of tuberculosis; that is, one which hinders the development of the culture, causes necrobiosis of the tubercle bacilli and renders inert the tubercle bacilli that have been injected into them along with the control animals. The blood serum acquires special antitoxic properties toward the tuberculous poisons and protects guinea-pigs from a deadly dose of the same. It also acquires agglutinating power. All these changes are indications of attained immunization.

Koch, and his school, attach great importance to agglutination which they depend upon as the sign of the advent of immunization. I recognize its importance as it runs parallel to the development of the bactericidal properties of the serum. But I hold that the demonstration of the existence of this property is even more convincing.

Out of it all stands forth the fact that we have a direct method of showing attained immunization, and, thanks to the proof of the resistance of the animal to the bacilli injected into the veins, an indirect method of showing the value of the defensive substances produced in immunized animals.

In animals, immunization may be obtained with different procedures, and may be either active or passive as is the case in any other infection.

The method most commonly followed for the production of active immunization against tuberculosis in animals is that of progressive injections of bacteria of variously attenuated virulence. This method has given good results and has been as successful in my school as in that of Behring and of Koch. It is, however, a method that is difficult to carry out because one does not always hit the exact dosage, and then the animal is lost or immunization does not take place. And for this reason it has not succeeded and does not succeed in the hands of many observers.

A more certain method of active immunization is that of inoculation with dead bodies of the bacilli properly prepared, sometimes used whole, and sometimes macerated in warm water. With this procedure good results have been obtained, and long experience has shown that the injection

of very little material is required for the production of a large amount of defensive material in the animal organism.

Another method of active immunization which has been recently used by us, and which has given the best results, is that based upon the use of what we call bacillary pulp. This bacillary pulp consists of the juice of very virulent bacilli which we obtain by expression and subsequent passage through the Chamberland filter.

We thus have a juice which in all the tests made is shown to be absolutely free from bacilli, a juice of bacilli which has been in no way changed by chemical agents or by heat. This juice produces satisfactory immunization, causes the formation of defensive substances in large quantities, especially of antibodies, and can be easily standardized. It has all the characteristics of living bacteria without any of the disadvantages. And considering the fact that the bacilli act only through their toxins it is easy to see how it can be reasonably substituted for the bacilli. But, setting aside all doctrinal considerations the fact stands out that immunization by this means progresses rapidly and with safety. By this method we have also been able to immunize guinea-pigs and rabbits, and have obtained in guinea-pigs sera with an agglutinating power of from 1 to 1000, and in rabbits from 1 to 2000.

Passive immunization may be obtained for tuberculosis as it is for other infections, by introducing into the animals under experiment, defensive substances, antibodies, and antitoxins, obtained by proper treatment from another animal.

In reality this immunization is not wholly passive. It arises, without doubt, in the animal organism through the energies of the organism itself; this is proven by the fact, as I have shown, and as may be found by any one who proceeds according to my method, that the antibodies and antitoxins exist in the blood of animals thus injected in much larger quantities than was injected. Guinea-pigs and rabbits thus treated attain the power of withstanding endovenous injections of a quantity of virulent culture that surely would kill the control animals in four or five weeks.

Introduction of these materials is made by injection of the serum containing them subcutaneously and intravenously and may be accomplished through the digestive tract. This latter is a part of our more recent studies which deserves further investigation, on account of the importance that it may have in human practice, and on account of the immediate possibility of its application to man.

The passage into the blood of materials for defense against bacterial infection, by way of the digestive tract, has been hardly studied at all until now, and it opens up an entirely new and almost unexplored field of research. The most conclusive studies are all Italian. There are those of Prof. Sclavo, who has demonstrated the possibility of introducing diphtheritic antitoxins by the digestive tract and of developing their immunizing action in animals, and those of my school in respect to the absorption by the digestive tract of antitoxin and tuberculous antibodies.

I shall set aside all doctrinal questions to which this might refer, convinced, as you will be, that the facts are worth more than all the discussions, and I will tell you what I have seen.

The first idea of resorting to the digestive tract for the introduction of antitoxins and tubercular antibodies came to me when confronted with some patients who opposed the injection of serum.

The results impressed me because I saw antituberculous substances increase in their blood at the same time that I observed develop in them analogous effects to those which I had seen with serum injections.

Struck by this fact, which I made public in 1898, researches in connection with it were undertaken in my laboratory. A first series of examinations showed that not only the serum of the blood but above all the blood clot, that is, the conglomeration of red and white blood corpuscles, contained the immunizing substances in large quantities. The next step was as follows: there was drawn from the jugular veins of an immunized animal (horse, cow) a certain amount of blood. Part of this was allowed to coagulate in a sterile vessel, in order to gather the separated serum. Another part was rapidly defibrinated, and the serum was collected in a few minutes by centrifugalization. The sediment was then repeatedly washed with a physiological salt solution, and an extract prepared using an amount of distilled water, equal to the serum extract. After forty-eight hours the agglutinating power of the three preparations was estimated in comparison with homogeneous cultures of tubercle bacilli (method of Courmont and Arloing), and the antitoxic power in comparison with the *text-gift*.

If the antitoxin and the agglutinating power were free in the circulating plasma, the agglutinating and antitoxic power of the serum of centrifugalization ought to be equal to that of the separated serum, and there ought to be little or no agglutinating and antitoxic power in the aqueous extract of the corpuscles.

However, in all the trials of centrifugalization, the serum which had stood the least time outside of the organism in contact with the cellular part of the blood was shown to possess a markedly inferior agglutinating power to that of the separated serum (the serum remained for a long time, forty-eight hours in contact with the cellular part of the blood) obtained by the coagulation of the blood of the same animal.

The aqueous extract of the corpuscles always has had an agglutinating power distinctly superior to that of the serum of centrifugalization in the same animal; and equal, and sometimes superior to the agglutinating power of the separated serum of the same animal.

To sum up, so far as the agglutinin is concerned, the lower the power in the serum of centrifugalization, the higher is it in the extract of the corpuscles; and while there is a marked difference between agglutinin contents of the serum

of centrifugalization and the separated serum, there is little difference between the separated serum and the extract of the coagula, although this latter has been shown to be always perceptibly richer.

So far as antitoxic value is concerned the extract of the coagula and the separated serum always show themselves endowed with a high value, equal to 1,000 antitoxic units; that is to say, capable of saving as much the one as the other when injected under the skin in the proportion of one to one thousand of weight, the healthy guinea-pig having been given a mortal dose of tuberculin, while, on the other hand, for the centrifugalized serum it was necessary to save a healthy guinea-pig from the same mortal dose of *text-gift* to inject in one instance in the proportion of two thousand, and in three other cases in the proportion of one to five thousand, that is to say, showing it possessed from 500 to 200 U. A.

The results obtained lead us to believe that the tuberculous antitoxins and agglutinins although found circulating freely in the plasma, are only found in very small quantities, and that therefore they must hold a more or less intimate relationship to the figured elements of the blood. And as it appears that the faculty of producing these substances cannot be attributed to the red corpuscles of the blood; on account of their specific physiological function we must hold that it belongs to the leucocytes of the blood.

In pursuit of this knowledge we have methodically fed guinea-pigs, rabbits, dogs and asses with this substance. To a series of guinea-pigs we gave daily by the digestive tract three grams of this tuberculous antitoxin for about one hundred days. Before the experiment, having bled from the carotid, we measured the agglutinating power and found it wholly negative; after fifty days of treatment the sera of these guinea-pigs had agglutinating powers that ranged from a minimum of 1 :15 to a maximum of 1 :30. After one hundred days of treatment the sera of these guinea-pigs presented an agglutinating power of 1 :25, 1 :40, and finally, 1 :50. These guinea-pigs were divided into two series. In the first series we injected into the veins living virulent bacilli in the proportion of 2 milligrams to each animal. In the other series we injected a deadly dose of test poison.

Of the guinea-pigs injected with living bacilli in the veins, some lived sixty, some ninety days, while an equal number of control guinea-pigs of the same weight injected in the veins with the same dose of the same bacilli all died within twenty-five days with marked emaciation. At the autopsy of the former there was found circumscribed pulmonary tuberculosis, and tuberculosis of the lymphatic glands, while in the controls there was most acute diffuse tuberculosis. In the second series with subcutaneous injection of test poison in the dose of 1 :100, all triumphed victoriously over the poison; while an equal number of control guinea-pigs injected with the same quantity of the same tuberculin all died in from three to five days.

To a series of rabbits there were fed daily four grams of antitoxin; all these rabbits before the experiment showed neither antitoxic nor agglutinating powers in their sera. They were subjected to this treatment for about sixty days. At the end of that time the agglutinating power of their sera was from 1 :50, and in some from 1 :60. the antitoxic power was equal to 330 antotoxic units; this serum injected in a dose of 5 :100 subcutaneously in a healthy guinea-pig saved it from a deadly dose of test poison. The rabbits thus immunized, together with the same number of control rabbits, each received in the marginal vein of the ear five centigrams of living and virulent tubercle bacilli.

The controls all died in eighteen to twenty-five days with marked emaciation (some had lost more than a third of their weight) and the autopsy showed diffuse miliary tuberculosis in the liver and lungs.

The rabbits previously subjected to the treatment with antitoxin by way of the stomach, easily overcame the injection of living bacilli. At first they lost weight and then they gained, and when they were killed about three months later they were in a general condition of robust health, and at the autopsy there was no sign of tuberculosis.

Also in a series of dogs immunization was practised against tuberculosis, by way of the stomach. To these dogs were given daily mixed with their food five grams each of antitoxin. The dogs thus treated developed in their sera conspicuous agglutinating and antitoxic properties. Before the commencement of the treatment each dog was tested for the agglutinating and antitoxic power of its serum by bleeding from the carotid. In not one, notwithstanding repeated experiments, was any antitoxic property found in the sera, at least in any degree that was appreciable by the methods employed. Besides it may be said that the agglutinating power of the serum of the majority of dogs has been found negative; although some have shown a very small agglutinating power equal to 1 :5 and the highest to 1 :10.

The duration of treatment was about three months; after two months, on bleeding these dogs and measuring with the Courmont-Arloing method the serum was found to have agglutinating powers, ranging from 1 :50 to 1 :100 and antitoxic value equal to 200 antitoxic units.

At the end of this treatment, that is, after the dogs had taken antitoxin by the stomach for three months, the agglutinating and antitoxic power of their serum was again tested, and it was found that it had been much augmented, amounting in all the dogs to a value of 1 : 200 and even more.

The increase of agglutinating power was accompanied step by step by antitoxic power. The sera of all these dogs had attained so high an antitoxic value that injection of a dose of two per cent. under the skin of healthy guinea-pigs saved them from test poison; these sera had obtained an antitoxic value equal to 500 units.

It was likewise found with the dogs that their organisms presented resistance to bacillary infection, after their sera, as in the rabbits and guinea-pigs, had shown the presence of a conspicuous amount of antitoxic and agglutinating substances.

In these dogs, and in the others under control, all of about the same weight, there was injected into the vein of the foot 30 centigrams of living virulent bacilli in an emulsion of physiological serum.

Some days after the injections all the dogs began to show emaciation, quite marked in those that were not immune, but less notable in those that were immune, and these latter, after a period of about twenty days of general ill-health, recovered completely and all gained weight perceptibly. At the point of injection there was no reaction whatever, and after fifteen days one could not, upon inspection, see the point on the vein in which the needle was introduced.

But quite different, on the other hand, were the fortunes of the control dogs; at first inflammatory processes were noted, and then ulcerations at the point of injection, with necrosis and conspicuous loss of tissue; these ulcers continually presented a superficial torpid granulating surface which never healed, notwithstanding proper local applications.

In the dogs of this series (the controls) the emaciation, marked from the beginning, continued progressively and in a state of marasmus reached during a period of from 40 to 60 days a marked loss according to the body weight; in some the loss amounting to almost half the original body weight.

At the autopsy there were found active tuberculous processes at the point of injection, tuberculosis of the neighboring ganglia, of the mesentery, liver, spleen, and to a slight degree of the lungs. None of the immunized dogs, which gradually, one by one, were killed after a period of from two to four months, showed any signs of tuberculosis.

In the asses to which were fed daily twenty-five grams of antitoxin by the stomach a considerable increase of agglutinating and antitoxic power of their sera ensued. In them it was observed that ingestion of this substance produced decided well-being and a noticeable increase in weight. Their sera, examined at intervals, presented a conspicuous development of agglutinating and antitoxic substances. Before beginning the treatment each was accurately tested, for antitoxic and agglutinating power of their serum, by the methods indicated, and in no case was agglutinin and specific antitoxin found to be present.

In the first experiment made, about fifty days after the beginning of the treatment, we found agglutinating powers in the serum, ranging from a minimum of 1:50 to a maximum of 1:150, and antitoxic powers varying from 100 to 200 antitoxic units. After four months all the asses were bled again, and we found in their sera decided presence of agglutinating and antitoxic substances. They possessed agglutinating powers which amounted to about 1:200, and antitoxic powers equal to 500 antitoxic units.

The experiments here related are therefore positive proof that defensive antituberculous materials are absorbed by the digestive tract, and that they confer upon the animals to which they have been fed a resistance against tuberculosis. And they are absorbed independently of the age of the animals.

In like manner the milk of cows which have been immunized against tuberculosis contains defensive materials, and when administered by way of the digestive tract, confers upon the animals nourished by it immunizing properties.

The question of the passage of immunizing materials against infection in general into the milk is one that has come to be much discussed of late, more on the score of reasonableness than as a positive fact. Here, as in the beginning, setting aside all doctrinal debates, I will only say that so far as antituberculous defensive materials are concerned, they positively do pass into the milk, and I make the statement as the result of our investigations.

We have in fact immunized two milch cows with the juice of dead macerated bacilli, according to the methods we have habitually followed, studying during the time their milk, both as to its agglutinating power on a homogeneous culture of tuberculosis and its antitoxic power over *test-gift*.

Step by step, as we proceeded in the immunization we saw appear in the serum of their milk, when properly prepared, agglutinating powers which developed progressively, increasing in a parallel line with that of the serum of the blood, and maintaining approximately a relation of 1 to 5; that is, the agglutinating value of the serum of the milk was a fifth less than the agglutinating value of the serum of the blood.

We likewise have been able to establish the presence of agglutinin in the milk of the immune female rabbit, and relatively to that in the blood, in a measure in even greater quantity than in the milk of the cow.

It is certain that the antitoxins pass into the milk, and agglutinin in greater proportions than the rest. The proportion between the antitoxin contained in the milk and that contained in the blood we have found to be as 5 to 10.

All of these proofs were made according to the methods we have already spoken of, and there is no doubt whatever concerning this fact, namely, that the antibodies and bacillary antitoxins contained in the blood of immunized females pass into their milk.

If, then, we feed sterile animals with this milk, we find, as we would expect after the experiments we have just described, that the defensive material becomes absorbed in the digestive tract and passes into the circulation.

We have fed eight-day-old calves for four months with milk from an immunized cow, the serum of whose milk had an agglutinating power of 1 to 40, and an antitoxic power of 1 to 700.

The blood of these calves before they were fed on the milk had neither antitoxic nor agglutinating powers. However, the serum of the blood of these calves after having used for four months the milk of immunized cows, acquired an agglutinating power of 1 to 70 and an antitoxic power equivalent to 1,000 antitoxic units to the cubic centimeter.

Behring in a conference held a year ago in Vienna, inquired whether antituberculous materials pass into the milk, and whether they can be absorbed by the digestive tract.

Our first answer to this question was given even before he had asked it, because our communication was made in 1902 to the Congress of International Medicine in Rome. These later studies which I now report, give the answer in full.

Further research will better define the qualifications of the fact, but the fact itself stands, and has an importance from which there is no escape.

It therefore enables me to affirm that immunizing materials can also be introduced into the animal organism by means of the gastro-enteric canal, and be utilized for passive immunization.

As we have seen, the ways in which immunization can be attained are numerous, no special bacilli nor obscure processes being necessary as there would appear to be on reading what Behring has said in his address. It is only necessary to employ good products and to acquire that experience which comes to those who work constantly at a given subject.

In view of the now indisputable fact of the possibility of immunizing animals against tuberculosis it is natural to ask why can we not obtain the same results in man, and create thus in his body a certain resistance to tuberculous infection. It is this problem that engrosses me at the present time, and has absorbed all my energies.

I have examined every possible means of immunization adopted for animals. I have discarded active immunization by means of endovenous injections of attenuated living bacilli. This is a procedure which we will never be able to adopt in practice. Though it is true that Möller, the director of the sanitarium at Belzig, near Berlin, has tried endovenous injections of the bacilli of tuberculosis which had been attenuated in the body of the crocodile, and has had no bad results from them, nevertheless, in spite of his example, I repeat, this method of immunization will never enter into human practise. I could never advise it. Inasmuch as my studies have clearly shown that the action of the bacilli depends upon the toxic substances contained in their protoplasm, and in the toxins secreted by them; and since it is possible to produce antitoxin and antibodies by means of injections of these materials only, I neither see nor comprehend the necessity of injecting living cultures, no matter how much attenuated. We must not forget that the resistance of the tissues to tubercle bacilli varies with each person, and what might happen in such a case might be, as has been seen in animals by many experimenters, the production of a tuberculosis as the result of an injection of active bacilli, intended for immunization.

Passive immunization by introducing into the human body immunizing substances prepared in the body of healthy animals by the methods which I have already indicated, is the method which certainly seems, the most easily attained for man.

By injections of sera rich in antitoxin it is possible to confer upon the human body a very high degree of immunization, both through the substances introduced and through those which the substances introduced provoke the production of in the human body itself.

If we measure the antitoxic, antibacterial and agglutinating powers of the blood serum of a man after a period of injections into his blood serum from an immunized animal, we find that we have raised the standard very high. The antitoxic power may reach and even surpass 1,000 antitoxic units per cubic centimeter, while the agglutinating power reaches the figure of 80 to 100.

These facts prove that immunization has taken place, and show that the same thing happens in man as in animals when treated in the same manner, the latter thus becoming refractory to the endovenous injections of virulent tubercle bacilli which kill control animals.

In man, we have never made this test and will never make it. The analogy to what happens in animals is, however, a sufficient proof of it.

In addition, we have a proof in men suffering with tuberculosis, and who have been healed by injections of therapeutic serum, that is quite analogous.

In these subjects, who in consequence of such injections given have been permanently cured, the serum by developing a therapeutic action has evidently also caused immunization, because without this they would have had a reinfection in an organic soil which had lost its defensive powers or the capacity to produce one. And, this is a fact to which until now sufficient attention has not been given, and which therefore deserves to be considered.

In view of the wide diffusion of tubercle bacilli it must be held that if a subject cured of tuberculosis does not become reinfected, it signifies that his organic soil has become modified in such a way as to be able to withstand a new infection. If this were not true, he would again become infected.

Now, of these subjects who have been injected there are many who have been permanently cured for ten years, and a number of them are from time to time under observation in my clinic. In this connection it would be interesting to tell the story of a tuberculous family observed in my polyclinical service. In this family the mother had had a brother and two sisters who had died of tuberculosis. She, however, was well. The father was born of healthy parents. From this marriage 12 children were born. One died of diphtheria at

three years of age, the other 11 were all tuberculous. Of these, four had already died before the family came under my observation. The other seven all came to my polyclinic, and all showed pulmonary tuberculosis in different stages. They were immediately subjected to passive immunization with progressive injections of antitoxin; to-day they are all in excellent condition, showing nothing wrong in the respiratory tract. The immunization has lasted for three years, during which time the patients have worked and lived in miserable hygienic conditions. They went to work and were exposed to all sorts of weather. This is a significant illustration, on account of the number of the individuals and the family to which they belong.

Indeed analogous results may be obtained in man by the introduction of defensive materials by way of the digestive tract, with serum, with blood coagula, with milk, and most probably with the flesh of immunized animals.

In the test subjects to which we have administered antitoxin and antibodies by the mouth, we have seen the agglutinating power mount from zero to fifty, and the antitoxic unit from an insignificant fraction per cubic centimeter to 200.

This shows that also in man agglutinin and antitoxin administered by way of the stomach pass into the circulation and stimulate the formation of other agglutinins. The same thing happens, therefore, in man that happens in animals which, as we have already seen under the same treatment, become refractory to endovenous injections of virulent bacilli.

Behring, in the past year, after having finally discovered what I had discovered nine years before, namely, the presence of antitoxin and antibodies in the blood of immunized animals, expressed the hope that such substances might possibly be used in milk for human prophylaxis. He expressed simply a hope because, as he announced, he then had not had any actual experience in the matter. This hope, as a result of our studies that have already been published, had been realized before he had even expressed it. Our investigations show that it is quite possible to get a certain degree of immunization by means of the digestive tract in adults; this point is emphasized because Behring held that it might be hoped for only in infants.

Another method of possible immunization in man which I have studied and which is also efficacious, is a method of mixed immunization, first passive, then active, which we call progressive immunization.

The following is the method by which I proceed: I give first of all a series of injections of a cubic centimeter of serum rich in antitoxin and antibodies for a period of twenty days on alternate days. Then, during the second period, I inject the same serum added to an extract of macerated tubercle bacilli in a progressively increasing quantity. I begin by making five injections with serum that contains a milligram of extract to the cubic centimeter, and thereafter consecutively five injections with two milligrams, five with three milligrams, five with four milligrams and five with five milligrams, always using one to each cubic centimeter.

Following this comes a third period in which I inject the extract of bacilli in aqueous solution by itself and in a progressively increasing dose; that is, five injections to a milligram per cubic centimeter, five to two, five to three, five to four, five to five.

In this manner, after a period varying from three to four months, there develops in the blood of man a considerable quantity of antitoxins, bactericidal materials and agglutinating materials. Men in whom there had been an agglutinating power of from one to five reached the point of having an agglutinating power of from 1 to 100, which to any one who has had experience in such studies, is a rather high power of agglutination. Naturally, in these men I did not make any injection of living bacilli to see by direct test whether immunization had actually taken place, but I can only say that animals treated in the same manner and with the same strength proved resistant to injections of a culture of living bacilli. The animals also had antitoxic, bactericidal and agglutinating materials in the blood.

I have lately studied a method for man that is very promising and easy of attainment. I was led to this by what I had observed in my studies of the efficacy of the dead bodies of the bacilli in the production of immunity; and I took as a keynote this fundamental principle: *Create a peripheral focus of tuberculous inflammation without living tubercle bacilli and bring about by this means the active production of defensive materials. In this way a true vaccination may be practised.*

I have adopted such a method in man, after having controlled it in animals. In the animals treated in this manner, I had the usual results; that is, resistance to the culture of living bacilli, the production of defensive materials, and a high agglutinating power. In man I have observed analogous results, with the exception of the resistance to living bacilli which I have not proven. I will tell you in detail what happens. The part used for the injection is the same as in Jennerian vaccination, the arm. A superficial subcutaneous injection, but exceedingly superficial, is made in the arm with a small quantity of vaccine material. A fever develops. Let me illustrate by some cases: Two children habitually feverish have had these injections. One of them on the day following the injection had an elevation of temperature which reached 100.7° F., with a corresponding acceleration of the pulse. The day after there was again a slight elevation. The fourth day after, the temperature again went up, then the thermic curve ended in a complete fall. No other phenomena of general disturbance occurred outside of that of a slight feverishness. In the other child, on the day following the injections the fever reached 101.9° F. and

lasted two days and then fell. The course of the pulse also followed the thermic curve. The same thing happened in several other infants which I injected in this way. There is a local formation of a small abscess which is limited and completely sterile. There results a small purulent focus which if the injection is even slightly deep requires some time to heal. We have had some that lasted three or four months before they were completely healed. In the meantime there is a progressive increase of agglutinating power. For example, a child that had an injection on March 1, 1903, with an agglutinating power of from 1 to 10, had already reached on April 10 an agglutinating power of 1 to 20, June 15 of 1 to 25, July 20 of 1 to 60, and October 15 of 1 to 100. The most important feature of this is the progressive increase, because it shows that defensive substances are being continuously elaborated. The interpretation placed upon it may or may not be true, but the fact is that the increase of agglutinating power is progressive, and has been so in the whole series of subjects that I have injected. I cannot ascertain whether or not these children are now capable of resisting an injection of virulent tubercle bacilli, because I have not wished to make such a test upon them, but I have the most important criterion of analogy. The animals thus treated and which have presented the same phenomena, the increase of agglutinating and antitoxic power and bactericidal power, were able to withstand endovenous injections of a virulent tuberculous culture. In addition the human clinic furnishes us data which confirm these experimental facts.

We often see that when a focus of tuberculosis is completely healed in man he remains permanently immune against tuberculosis. There are cases of surgical tuberculosis which quite clearly establish this fact, since, as a rule, when they are cured, tuberculous foci do not again show themselves elsewhere. And in families in which tuberculosis is prevalent we see that the only ones that survive the other members are those who have articular tuberculosis and have been cured of it. In subjects that have had cutaneous tuberculosis the same thing usually occurs. There have also been similar examples in visceral tuberculosis.

There are many cases of peritoneal, pleural and pulmonary tuberculosis cured in patients who have never afterward had any tuberculous foci in any part.

When an individual is completely and surely cured of a focus of pulmonary tuberculosis and sclerosis of the area previously affected has taken place, we see that he remains habitually and permanently immune. I say completely and surely cured because there is no need to confound with cure that improvement of the general condition that is due to the neutralization of the tuberculous toxins while locally the lesions persist and continue.

These cases are so many more examples of what the casuistic clinic furnishes us in subjects immunized against tuberculosis by having had an attack of curable tuberculosis, and having been cured of it.

I say immune, as I have already observed, because the organic soil in which tuberculosis has once struck root would, if not modified, retain susceptibility to a subsequent implantation.

All these researches and all these facts prove positively that it is possible in several ways to produce specific immunizing substances in a healthy man, which increasing naturally augment very decidedly the resistance of the body to tuberculosis.

Will this increase of resistance be sufficient? How long will it last?

I cannot answer this question yet; it is necessary now to carry on researches in that direction. And since the system of vaccination that I have devised is innocuous its application on a large scale would furnish many useful data. By practising this vaccination in families where tuberculosis is prevalent, practising it on a large scale in factories and in industrial centers in which tuberculosis makes havoc, we might perhaps be able to see very soon what value it may have.

My colleagues, I believe that I can foresee this. There are already some possibilities of carrying on these studies on a large scale.

Since milk, the blood serum, the blood and probably also the flesh of immune animals can furnish the human organism with elements of resistance against tuberculosis, why should not these be used as food and furnish along with the normal nutritive material immunizing material?

Why, instead of ordinary milk, should we not use the milk of an immune cow? Why, instead of ordinary meat, should we not eat the flesh of immune animals? On these points scientific investigations are already sufficiently advanced to be of benefit to humanity.

The struggle against tuberculosis, it must be remembered, cannot be efficacious unless it succeeds in curing the organism of it. All the means thought of to destroy the bacilli have fallen short of anything decisive, just as sanitary restrictions have failed in the case of other infections.

The victims of tuberculosis will diminish in number in proportion as the human organism is in condition to resist the disease. In this proposition lies the whole secret of success.

Here in your great country, in which there is so much initiative, here ought to be born a great movement for the practical application to normal daily life of all the scientific truths which we now possess for training the organism to struggle against tuberculosis.

And if this treatise of mine brings forth this as a result, the awakening in America of a great movement of this kind, it certainly will accomplish its highest purpose. And if this movement should originate in your noble institution, your institution will have reached the highest goal to which it can aspire, the goal of redeeming humanity from tuberculosis. I leave you with the faith and hope that this may come to pass.

THE TREATMENT OF NEURASTHENIA.*

BY HOWELL T. PERSHING, M.D.,
OF DENVER, COLO.

There is one fundamental principle which furnishes the reason for every step in the treatment of a neurasthenic patient. The nervous system is a mechanism, and, like the simplest machine it receives a limited amount of energy and expends it. Under normal conditions the amount of energy received has slightly exceeded the amount expended, so that a certain reserve has been accumulated, more or less of which will be used during periods of unusual activity, to be promptly restored during rest. An exhausted nervous system has been so excessively active that food and oxygen have not been able to restore the depleted reserve, and so, whenever a vigorous and sustained action is called for, the machine works badly. It is like a storage battery that has been discharged too rapidly or for too long a time. Accordingly, whatever tends either to check the loss of nervous energy or to increase its income, providing it is not incidentally harmful, is a remedy for neurasthenia.

But, although this principle is clear and simple, its application is generally difficult and intricate. Increase in food and oxygen is indicated, but the increase may not be utilized. An overexhausted storage battery is so impaired that it cannot at once receive a full charge of electricity, and an exhausted nervous system may fail both to control digestion and to assimilate what is digested and brought to it. Rest is plainly indicated but the most stringent abstention from work will be of little or no avail if the more exhausting process of fear or worry is allowed to go on. Accordingly, we have no specific for neurasthenia; there is no magic drug or food, no form of electricity or radial activity, no plan of rest and isolation, no system of mental therapeutics on which we may exclusively rely.

When a difficult thing is to be done there is generally a special combination of resources that will succeed, although each taken singly is futile. To open the door of a safe you must have the right figures rightly arranged, and to get more than an occasional success in treating neurasthenia we must have a combination of favorable influences especially adapted to each individual patient.

Theoretically, the combination should be determined by the condition and individual peculiarities of the patient alone, but the physician is also a person, with his own peculiar resources and limitations, and the treatment must to a great extent be determined by his characteristics. For example, the physician who is buoyant and optimistic will depend largely on the favorable mental influence he exerts while the one whose chief characteristic is scientific accuracy will depend on the physical side of treatment and only secondarily exert a favorable mental influence. Just as no two artists can portray the same person in the same way, so no two physicians can treat the same case of neurasthenia in the same way.

In accord with the fundamental principle we should attempt to divide all remedies into those which, like rest, diminish the expenditure of nervous energy and those which, like food, increases its income. This can be done only roughly, for some remedies are helpful in both ways and others, like electricity, are known to be useful but in ways that are indirect and obscure. Making these allowances, our resources may be tabulated as follows:

I. Remedies whose chief effect is to prevent the loss of nervous energy. (A) Prevention of emotional disturbances; (1) By reassurance and favorable suggestion; (2) By forming the habit of muscular relaxation and repose. (B) Limitation of work. (C) Prevention of toxic conditions. (D) Removal of peripheral irritations. (E) Reduction of cortical irritability by medicines. (F) Sleep.

II. Remedies whose chief effect is to increase the income of nervous energy. (A) Food. (B) Medicines.

III. Remedies used empirically whose action is complex or obscure: Electricity, massage, hydrotherapy, exercise, change of climate.

Emotional Disturbances.—In most cases of neurasthenia the most persistent source of exhaustion is disordered emotion. Beside the ordinary griefs, anxieties, vexations and fears, the neurasthenic has a great many which a normal person cannot understand. There is a long list of diseases, ranging from varicocele to insanity, one or more of which he may imagine to be fastening itself upon him. Experience of the most ordinary kind, such as purchasing a ticket, getting on a car, walking in the street, talking to an acquaintance, and so on, may cause paroxysms of fear. An accidental association of ideas, as when the sight of a knife suggests the idea of stabbing a child, may by the very terror it arouses fix itself firmly in the mind and cause a pitiable fear that it may pass over into action. The inevitable annoyances of life have an exaggerated effect upon the neurasthenic and he reacts excessively to many trifling irritations which a normal person would scarcely notice; under their influence there is a tendency to assume a strained attitude in which the breathing is rapid and irregular and the muscles generally are tense. This condition is an exhausting one; patients often say that they do their best to hold their nervousness in but finally go to pieces. In these and many other ways disordered emotions involve a profound physical effect, draining the patient's strength and preventing its restoration.

The treatment of these disturbances begins with the examination and prognosis. Skilful questions and the careful physical examination convince the patient that his mysterious disease is now understood and the assurance that the case is one of nervous fatigue, that there is no organic disease, no sexual disorder, no danger of insanity, etc., and that the annoying symptoms will no doubt

* Read before the Colorado State Medical Society.

disappear under proper treatment at once places him upon a higher emotional plane. Fear and despondency thus banished will return but repetition of the reassurance will again succeed and for a longer time.

But, although it is of great importance to remove the ideas which might rationally cause a depressing emotion, this is not always sufficient, for such emotions often persist without any rational cause. The neurasthenic knows very well that an inappropriate question ought not to irritate him, yet it may set off an explosion of anger; he knows there is nothing to fear, yet feels horribly afraid. A very valuable resource in controlling a depressing emotion consists in the voluntary suppression of its motor reaction and the imitation of the attitudes and actions which express the opposite emotion. Thus the school-boy about to declaim, who would like to sink through the stage, steadies his trembling limbs, holds himself erect and forces loud tones from his quavering larynx; and in doing so he does not merely conceal his fear, he to a great extent dispels it by displacing the sensations of fear with the sensations of courage. Every neurasthenic should be taught to treat his fears, rational and irrational, in the same way. Too much should not be expected of this artificial courage at first, but if judiciously cultivated it will rapidly develop power for good. On the same principle, the neurasthenic should be taught to avoid the motor reaction to small annoyances and anxieties by breathing easily and slowly, by relaxing all his muscles except those whose activity is really needed, by speaking calmly, in short, by assuming the attitude and expression of complete serenity and repose.

Rest.—The prohibition of work is an obvious remedy for neurasthenia, sometimes too obvious, for it has great disadvantages and is often used to no purpose. The physician must carefully consider the relative importance of work and worry, and to what extent one is dependent on the other. It is very easy to tell a patient that he must drop everything and get away, but this is often a shirking of responsibility. In many cases it is far wiser to keep the patient doing a reasonable amount of work, enabling him to do it by removing as far as possible all other causes of exhaustion.

There are many other cases, however, especially those in which work has been a large factor in causing exhaustion or is inseparable from worry, that require the patient to give up work completely for a time, and unless he is to stay in bed the rest must be combined with agreeable recreation. It goes without saying that short hours for work and many vacations are eminently desirable but it is even more important that the patient should learn not to think of his cares and perplexities in the hours that ought to be devoted to rest or recreation. Everyone should cultivate a sport or hobby of some kind with which to crowd out inopportune thoughts.

Toxic Conditions.—In my experience the so-called uric acid diathesis is a very frequent complication of neurasthenia and much benefit is derived from treating it with an abundance of water and some compound of salicylic acid. Intestinal indigestion is also a frequent complication and although it is generally secondary to the nervous disturbance it should be palliated by appropriate nitrogenous diet, antiseptics (particularly salol) and mild laxatives. Purgation is very badly borne by neurasthenics. The excessive use of alcohol can only increase the degree of nervous exhaustion, if it does not lead to graver forms of disease. Theoretically the use of a strictly limited quantity, taken with food, might be beneficial, but in practice it is so difficult to secure the proper dosage that total abstinence is by far the best rule. The moderate use of tobacco is less likely to be harmful and may often be allowed. Neurasthenics, however, are especially sensitive to it and in some cases it must be given up altogether.

Coffee or tea should be allowed in any moderate amount to which the patient has been accustomed providing it does not interfere with sleep.

Peripheral Irritations.—The pain and annoyance due to disease in any part of the body may be a contributory cause of neurasthenia. The most important of such sources of irritation are disease of the intestine, anus or bladder, pelvic diseases of women, eye-strain and disease of the ear causing pain, tinnitus or vertigo. Such local diseases should generally be treated but their importance should not be exaggerated and severe measures must often be avoided or postponed. Strictly neurasthenic or hysteric pains must not be attributed to local disease; their treatment by local applications is almost invariably harmful because it fixes attention upon them and increases worry.

Reduction of Cortical Irritability.—In most cases the patient has become so sensitive to all unfavorable influences that even when sheltered from them to the utmost possible extent they still annoy and exhaust him. This is because the cerebral cortex is in a condition of irritable weakness and it is highly desirable that its irritability should be reduced. Many physicians try to do this by means of bromides but my own belief is that bromides continued for any length of time in efficient doses aggravate the disease. Codeine, in doses of one-fourth to one-half a grain three or four times daily, acts far more happily and helps toward a permanent cure. Opium in small doses, one-twelfth to one-fourth of a grain of the extract, is still more useful but in prescribing it the possible danger of the opium habit must be taken into account. It should be prescribed only in combination with other remedies, particularly strychnine and laxatives, so that the patient will have no discretion as to the size or frequency of the dose and will quickly get into trouble if he exceeds directions. This simple expedient almost wholly removes the danger. As a further safeguard the patient may be kept in ignorance of the ingredients of his prescription either by writing in such Latin as he cannot comprehend or by advising him not to read it for the general reason that any attention to the remedies exaggerates the symptoms. Opium is especially valuable in cases of morbid

fear and in those in which the recurrence of an agonizing idea makes the patient fear that he is becoming insane; in the latter it is indispensable. Unless the physician is convinced that the case is serious enough to justify the use of an opiate and confident of his own ability to use it skilfully he ought to withhold it and it should be discontinued as early as possible; but some cases are so serious and so obstinate that we cannot afford to reject so useful a remedy.

Sleep.—Neurasthenics should sleep as much as they can. If insomnia is troublesome at first it often yields to the combination of remedies chosen, without requiring the use of a direct hypnotic, which should always be avoided if possible. When wakefulness becomes a serious matter chloral is generally the best hypnotic; it is more efficient and less likely to cause depression of spirits next day than either sulphonal or trional. It should generally be omitted every second or third night and altogether discontinued as soon as possible.

Having reduced the waste of nervous energy to a minimum it will be much easier to increase its supply than if the latter alone were attempted.

Food.—The essentials in regard to food are that it should be abundant and taken at short intervals, that it should be rich in nitrogenous and phosphorized articles such as meat and eggs and that it should be eaten without fear of possible consequences. All theories about the stomach needing a rest must be ignored; it is the nervous system that must be rested and the digestive organs must be made to do their work. Anxious attention to diet does nothing but harm and digestive ferments seem to me to be altogether useless. On the other hand, strychnine, small doses of calomel and intestinal antiseptics are often of great service in aiding digestion. The weight should be recorded from time to time and its increase is a most valuable exhilarant for the patient who has been losing.

Medicines.—Many attempts have been made to supply nervous energy through drugs, on the whole with very little success. Phosphorus, phosphide of zinc and the hypophosphites I long ago discarded because they never seemed to be of the slightest use and the first two were generally distinctly harmful. The glycero-phosphates I have never tried, believing that if they are really useful the phosphorus compounds of eggs and meat are still better.

Strychnine probably stimulates the nutritive processes in the nerve cells and it seems to me to lessen the irritable weakness which is so characteristic of neurasthenia. Arsenic in its older, irritating forms is more likely to do harm than good, but as cacodylate of sodium it may be given much more freely and, with iron, is especially indicated in anemic patients. It is probably useful in other cases but I find it hard to be sure.

All neurasthenics are apt to infer from their bad feelings that their medicine is disagreeing with them and if the physician makes many changes on this account his usefulness will soon be at an end. Hence it is very important, in the early stage of treatment, to prescribe doses so small as to be absolutely safe and only for a very few days at a time. Then if there is any question as to the effect of the medicine one must insist that it is exactly right and that every bit be taken as originally ordered. The doses may be gradually increased according to need and when confidence has been established one may prescribe much more boldly.

Such remedies as electricity, massage, hydrotherapy, exercise and change of climate have been left to the last because I regard them as decidedly least in importance. Any of them may be used to advantage, especially for its psychic effect, as an adjuvant to a combination of the remedies already mentioned, but it would be a serious mistake to exalt it to the chief place. Most patients have a tendency greatly to exaggerate the physical action of remedies of this class and the physician ought gently to check this tendency. It is better to give the patient a rational explanation of the nature of his malady and a just idea of the proportionate value of remedies, thus guarding him from his morbid tendency to fads; the immediate effect of the mental impression may not be so brilliant but the permanent results will be far better.

Electricity.—In most cases of neurasthenia electricity may be used with distinct advantage although it is hard to say how much of its influence is mental and how much physical. I am in the habit of passing the galvanic current from the positive pole over either temple to the back of the neck on the opposite side, turning it on and off gradually and not exceeding a strength of three to five milliamperes. This may cause a little dizziness at first but tolerance for stronger currents is soon established and the applications seem to be especially useful in cases in which vertigo is a prominent symptom. The static breeze and spark are also useful, especially when applied to the seat of morbid sensations. The sensory stimulation seems to aid in replacing the morbid feelings by normal ones. Faradism may be made to serve the same purpose but as it is less convenient I do not use it except for diagnosis.

Massage.—I have had far less experience with massage than with electricity and wish to speak cautiously of it. Its effect in moving blood and lymph from the periphery toward the heart is well known and is of the greatest service in the rest cure during the time when active exercise is prohibited. The sensory stimulation may also be useful. The objections to it in ordinary cases are the extra expense, the time required, the fatigue involved and the danger that an enthusiastic and self-sufficient masseur will have a bad influence in presuming to give advice on matters altogether out of his province. In my own practice the objections have generally outweighed the advantages and the last objection has been most serious with masseurs recommended most highly by distinguished neurologists.

Hydrotherapy.—Although highly esteemed by men whose judgment commands respect hydro-

therapy is comparatively little used in this country. For neurasthenics the more elaborate methods have the same disadvantages as massage and are hardly applicable in private practice. The popular Turkish bath is generally harmful. On the other hand, a cool sponge bath in the morning is capable of doing a great deal of good, provided prompt reaction is secured and fatigue avoided. The water should not be too cold and with elderly patients the shock of cold water should always be avoided on account of the violent fluctuations of blood pressure caused by it. A comfortably warm bath at night may favor sleep and if it does there can be no objection to it.

Exercise.—The general principle of exercise is of great importance; its application, however, requires nice discrimination. I never allow my neurasthenic patients to go into a gymnasium or to take any form of so-called health exercises. On the other hand, every effort should be made to re-accustom the patient to his normal activities, first to his recreations, afterward to his work. For example, many patients say they can no longer read on account of the disturbance it causes. This real or fancied inability deprives them of a most valuable solace and diversion. In the absence of any serious disease of the eyes it is generally wise to instruct them to read for ten or fifteen minutes each day, no matter how unpleasant the effect may be nor how attention may wander, at the same time assuring them that only good can come of the attempt. The patient soon finds that he can read much more than he had thought possible and by gradually extending the time the ability to read in moderation is soon reacquired. Of course the physician must be careful not to demand too much at first for the avoidance of fear and of undue fatigue are essential. The same principle applies to walking, going about the city, meeting friends and, ultimately to work.

Climate.—Change of climate will generally be avoided if possible but it may be absolutely necessary when, as in the tropics or in malarial regions, the climatic conditions are an important factor in the causation of neurasthenia. There is a popular impression, shared to some extent by physicians, that the altitude of the Rocky Mountain region is a cause of neurasthenia and that persons becoming nervous here should forthwith "go to a lower altitude." This, I am quite sure, is a mistake, at least as far as altitudes of less than 7,000 feet are concerned. But if a patient in surroundings that are ordinarily healthful is to abandon his work for a time it may be well to consider whether removal to a different climate may not be advisable, provided good medical attendance and other necessary advantages can be obtained there. If a change is to be made those patients in whom irritability and restlessness predominate had better go to a moist, warm climate, while those who are languid and debilitated will do best in the dry, bracing air of mountain regions. In any event the place chosen must afford opportunities for agreeable rest and recreation.

The real difficulty in treating neurasthenia is not to know the remedies that may be used but to select and make effective that combination which best suits the individual patient, taking into account all his circumstances as well as the features of his disease. This problem the physician should approach in the spirit of an artist rather than in that of a pure scientist. He must select and emphasize some resources and ignore others. For his worst cases, if they can pay for it, he will generally choose the combination devised by S. Weir Mitchell and known as the rest cure. But if he does not have some of that great man's success in happily influencing the patient's mind, the rest, food, electricity and massage will do but little good and may even make matters worse. His greatest skill will be demanded by those who are not financially able to command the luxuries of the rest cure, who must continue at their work or return to it at the earliest possible moment, and yet must recover their health.

ABDOMINAL ASCITES WITH 150 TAPPINGS.

BY E. K. BROWD, M.D.,
OF NEW YORK;
ATTENDING GYNECOLOGIST ST. MARK'S HOSPITAL; ASSISTANT ATTENDING GYNECOLOGIST GERMAN POLYCLINIC.

Rosa W., Hungarian, sixty-nine years old; married when seventeen years old, widowed ten years; never been sick before. Mother died of cancer of the stomach at the age of sixty-nine years; father died when 102 years old, brother died of pneumonia when thirty-four years old; another living, sixty years of age; three sisters living, ages fifty, fifty-six and seventy years.

First menstruation when she was thirteen years old, regular. She had 12 children, last child twenty-five years ago; miscarriage of three months 23 years ago. Four children died, 8 living. Menopause at 50. She first became ill nine years ago with pain in the region of the liver, nausea, bilious vomiting and constipation; this pain in hepatic region shooting down into the right thigh and leg. Examination presents a slightly enlarged liver, painful to touch; heart, lungs and spleen normal. Microscopical examination of urine excludes kidney lesion; no diabetes. Vaginal examination presents slightly enlarged uterus, adnexa normal.

After a lapse of four months since this onset, patient's abdomen began to swell, ascites was gradually developing. No edema of legs present. At the end of five months the accumulation of abdominal fluid necessitated the first paracentesis, which took place in the year 1894 when 15 quarts of transparent straw-colored fluid were removed in one sitting. Patient rallied for a short time. Two months after her condition required a second tapping, which again withdrew about 15 quarts of fluid. Since this second tapping she kept fairly well with no advancing ascites for one year, when, in order to relieve dyspnea and obstruction to the organs, a third tapping was resorted to

and again 15 quarts of fluid removed. Since then patient has grown weaker, anemic and could not bear the presence of a large amount of fluid, which now accumulated more rapidly, say, about 10 quarts during every four weeks, and, therefore, systematic tappings every four weeks during the next five years and every two weeks for the following two years were found necessary. Amount of fluid at each sitting about 9½ quarts.

During the ten years of her ailment she has been tapped 150 times. Fluid from the abdominal cavity is of a pale straw color of specific gravity 1.015; has very slight amount of sediment after centrifugation and microscopically presents few leucocytes, some fat globules and few endothelial cells, staining shows no organisms present and no tubercle bacilli. Above tappings were done with a medium trochar, wound at the side of puncture healing perfectly. On several occasions attempts were made by me to insert a small drainage tube into the puncture opening and leave it in situ, but on each occasion symptoms of weakness and uneasiness on the part of the patient required its removal. Again, very slow removal of fluid through a small-sized canula did not bring about any decided change.

From the very beginning of the patient's ailment I have urged her to submit to a radical operation, but surgical interference has been refused, and this fact accounts for the numerous tappings performed on her during this long period. She is now in a fairly good condition, not bedridden save for a day or so after each tapping. She is quite active in her household and takes her bi-weekly tappings quite heroically and is willing to submit to this minor suffering rather than undergo the risk of an abdominal operation. Her temperature now is normal, pulse 92. Amount of urine discharged during twenty-four hours, about 48 ounces; acid reaction; spec. grav. 1.026, no casts; only small amount of earthy phosphates present. She has a slight edema of the legs, which disappears after each tapping. The circumference of her abdomen before tapping measures 47 inches; from the sternum to the pubes, 20 inches. After each tapping careful examination is made, but no tumor or neoplasm can be mapped out.

Her uterus is enlarged and presents a nodulated hard mass simulating a fibroid uterus. Adnexa could not be mapped out; no enlargement in the region of mesenteric glands to suggest mesenteric lesion as the cause of obstruction to the portal circulation. Syphilitic lesions excluded by the history of the patient. Long-standing of the disease and fair condition of the patient exclude cancer of peritoneum or neighboring organs or tuberculous peritonitis.

We can think of a neoplasm pressing upon the large veins and obstructing the return circulation, thus producing this pathological condition of dropsy. This is a tentative diagnosis of an ovarian cyst with formation of old adhesions. The necessity of an exploratory laparotomy has been urged by many medical men as well as gynecologists who had occasion to see this patient, among whom were the late Dr. Paul Mundé, Dr. H. Boldt, Dr. A. Brothers, Dr. Alfred Meyer and others.

The following figures present a medical curiosity: During the ten years of my patient's illness the first 3 tappings gave 45 quarts and next 147 tappings at 9½ quarts, 1,396½ quarts; or, together, 1,441½ quarts or 2,883 pints or fluid pounds; or 360⅜ gallons.

Scott reports (Anomalies of Medicine, Gould and Pyle, 1900) a case of ascites in which 928 pints of water were drawn in 24 successive tappings. Van Wy mentions 1,256 pounds of fluid being drawn from abdomen of a woman in five years. Kaltschmidt describes a case of ascites in which in 12 paracenteses 500 pounds of fluid were removed. In 1721 Morand reported 2 cases of ascites, in one of which by means of 57 paracenteses 970 pounds of fluid were drawn off in twenty-two months, in the other 1,708 pounds in ten months. There are several cases on record in which ovarian dropsies have weighed over 100 pounds. Blanchard mentions a uterine dropsy of 80 pounds. Philosophical Transactions contain account of a case of hydronephrosis in which there were 240 pounds of water in the sac.

This case presents several interesting points: (1) On account of numerous tappings and large and continuous accumulations of fluid a human body could produce. (2) The advanced age of the patient and tolerably good health, unimpaired by the long, continuous drain of the constitution and obstructive circulation to the vital organs. (3) The possibility of a permanent cure of this chronic abdominal ascites by a radical operation, which would tend to break up the old adhesions and fasten the omentum to the parietal peritoneum, thus relieving the obstructive portal circulation and establishing a peritoneal circulation.

GASTRO-ENTEROSTOMY WITHOUT A "LOOP."*

BY JOHN ROGERS, JR., M.D.,
OF NEW YORK;
VISITING SURGEON GOUVERNEUR HOSPITAL; ASSISTANT VISITING SURGEON ST. FRANCIS HOSPITAL, NEW YORK CITY.

The mortality of gastro-enterostomy is still so high that few medical men will consider the operation within the domain of practicable therapeutics. It is more often regarded as a proper means of providing euthanasia. But there is one group of statistics, that from Czerny's clinic in Heidelberg, which represents a particular method of operating, and which has given, in benign cases, a death rate of only five per cent., almost as low as that for the interval operation for appendicitis. It is the more worthy of emphasis as it seems to have received little notice in contemporary literature.

The success revealed in this group of statistics is due to the fact that the method of anastomosis preserves the proper anatomical relationship of

* *Author's abstract. Read before the New York Surgical Society, December 9, 1903.

the stomach and gut. In all the other eighty odd methods which have been advocated, except gastro-duodenostomy, this relationship has been violated. The causes of death as given in their usual order of frequency are: (1) Shock, collapse, asthenia or inanition, all practically the same when the debilitated condition of the patients usually considered ready for so grave an interference, is considered; (2) infection and peritonitis as the result of contamination during the operation or subsequently. There is a connection here with the most frequent causes of death in that the perfectly healthy peritoneum can take care of a great deal of sepsis, but the diseased abdomen of a weakly person is quite another matter. Nevertheless such excuses are not altogether valid, and there is room for improvement. (3) Pneumonia, an accident liable to occur like shock or collapse, after any operation on debilitated individuals, especially after the deep narcotization so often necessary to obtain relaxation in the presence of epigastric wounds. Such wounds also interfere afterwards with coughing and clearing of the respiratory tract. It has often been attributed to the inhalation of stomach contents during the operation, a possibility which should be avoidable by lavage just prior to the anesthesia. (4) The fourth most common cause of death, and in the minds of most surgeons it probably ranks much higher, is obstruction in one form or another. That accompanied by "vicious circle vomiting" is by far the most common and is dependent upon the escape of stomach contents into the proximal instead of the distal segment of the anastomosed gut. The lumen of the distal segment becomes displaced from its intended position opposite the opening in the stomach and seems to be mechanically occluded by the pressure against it of the distended adjoining proximal segment. There may also be a physiological factor in the process, as Chlumskij has shown by animal experimentation, that filling of the duodenum inhibits the peristalsis of the stomach. This accident caused a fatal ending in the second gastro-enterostomy on record, and the numerous modifications of the original method which have been introduced to avoid it, testify to its importance and reveal the dread of it as a factor in much of the other mortality. But complicated and time-wasting procedures, often involving multiple openings in the gut, with all their increased chances of sepsis, can be largely eliminated, and if, in consequence, the death rate can be brought down to five per cent., the operation should not be considered one of last resort.

All except two or possibly three of the methods are what might be called "loop" operations. That is, a loop of jejunum or ileum is carried in front of the colon, or behind it through its mesentery, and joined to the front or back of the stomach. The length or shortness of the loop, the relation of it and its legs to each other, or the stomach and isoperistalsis, are of some importance, as a loop operation is quite often the only one possible. To avoid dangerous vomiting, an ever present chance in this method, experience has demonstrated that the proximal leg of the loop must at least be long enough to escape tension, or compression of the colon; that a broad curve where it is attached to the stomach is better than a sharp angular one; that the principle of isoperistalsis should be observed; that the fistula should not exceed 1½ to 2 inches in length, for if it does the difficulties of suturing favor spur formation; that the fistula should not be smaller than the diameter of the gut for fear of cicatricial contraction; that it should be as near as possible to the greater curvature or in the most dependent portion of the stomach; and above all that there should be an enteroanastomosis at the base of the legs of the loop. Roux's method of gastro-enterostomy "en Y," one of the three which does not involve a loop, approaches the correct anatomical relationship, but aside from the dangers of vicious circle vomiting, which has occurred even in Roux's operation (apparently from error in technic), and of obstruction by volvulus of the loop or hernia over it of the rest of the intestine, there are also in all such methods the added risks dependent upon time-consuming procedures and multiple openings in the gut. The operation in two stages, of which the McGraw elastic ligature is the best known, though a reasonable guarantee against infection, if used with the "loop" possesses all the disadvantages of that method and some additional uncertainties. Of the great number of mechanical appliances which have been brought forward, the Murphy button is, of course, the best, and is occasionally almost indispensable. Its well-known tendency to fall into the stomach and remain there, especially when the line of anastomosis is reinforced by suture, even in spite of Hildebrand's and Weir's modification of the distal half of the button, is a very serious objection to its use. There is at least one case on record in which after death from hematemesis, subsequent to gastro-enterostomy, the button was found imbedded in an ulcer in the stomach. There are, to be sure, numerous instances of its indefinite retention without symptoms, one for 6½ years, but there are always unpleasant possibilities. Nevertheless in all loop operations in addition to the usual advantages of saving time, the button has a definite usefulness in a certain amount of protection against persistent vomiting. One surgeon of large experience informs me, that before he adopted it he lost many cases from this complication, but since using it regularly he has not, in some sixty or seventy gastro-enterostomies, had a single instance of the vicious circle difficulty (and he always used the loop method). His experience seems better than most operators, but at any rate, the presence of the button in the summit of the loop tends to prevent angular kinking. The great number of other devices of a similar nature shows the need of one which, unlike them, can be employed without risk of extravasation of intestinal contents at the time of introduction, or later; which establishes the desired fistula immediately; which is as quick in applica-

tion as the button, and is certain of not remaining in the stomach or duodenum. Until such an appliance is invented, and there is a real need of one, the suture remains as the preferable means of joining the stomach and gut, when time permits.

Of the remaining two methods not involving a loop, the first to be mentioned is gastro-duodenostomy. The union of the stomach with the descending duodenum, introduced by Billroth for restoring continuity after pylorectomy and improved by Kocher, had been utilized in certain cases of benign stenosis by Henle and then Villard, but lately has been advanced by Finney as a substitute for all gastro-jejunostomies. In the Finney operation, its prototype the Heinecke-Mikulicz pyloroplasty, is amplified by transposing the transverse anterior division of the pylorus into a horseshoe-shaped ∩ incision six to ten inches long through the under part of the pylorus and adjoining greater curvature of the stomach and descending portion of the duodenum. This large opening provides free drainage and is anatomically and physiologically correct, and when circumstances permit the few written reports and the many verbal ones I have heard, seem to favor it without qualification. But gastrojejunostomy, if only because it is simpler, is undoubtedly a necessity for the greater number of cases, and the method described by Petersen, as used in Czerny's clinic is the one I wish to call attention to. He reports 215 cases without a single instance of serious vomiting. It is based on the simple anatomical principle that the first few inches of the jejunum descend vertically behind the stomach without any turns, and in this part lie directly in contact with the posterior surface of the stomach, separated from it only by the non-vascular portion of the mesocolon.

The ordinary retrocolica posterior operation is performed by drawing the omentum and transverse colon out of the median epigastric wound, and stitching the margins of the exposed posterior surface of the stomach near the greater curvature, to the edges of a rent made in the mesocolon. Then the jejunum near its origin is held perpendicularly to the spine, and attached some two to four inches below its origin at the plica duodenojejunalis, to the exposed posterior surface of the stomach by a row of Lembert sutures placed transversely to the long axis of the gut, and in its free border. In front of this the stomach and intestine are opened with due precautions, and the fistula completed as usual with stitches or the Murphy button and surrounded externally by a continuation of the Lembert stitches. The proximity of the fistula to the plica is determined by the degree of dilatation of the stomach, and the location of the lower border of that viscus should therefore be noted as soon as the abdomen is opened. My own rather limited experience with this method has been in favor of suture only, but if time is limited, then the button reinforced by suture externally. The jejunum is thus anastomosed to the posterior surface of the stomach in its normal descending position and without any twists. There is no loop to become occluded, and no chance for vovulus or hernia above it.

The following cases serve well to illustrate the application of this method. They were all operated upon in the St. Francis Hospital:

Case I.—M. H., thirty-years old, laborer; presented all the symptoms of pyloric cancer with an epigastric tumor, persistent vomiting and pain. In addition he had pulmonary phthisis. Operation July 27, 1903, by the Czerny-Petersen method with a Murphy button reinforced by sutures. The anastomosis was accomplished at a point about two inches from the beginning of the jejunum. Recovery uneventful; liquid food was given the following morning or within fourteen hours. Thereafter there was no pain and no vomiting, and the patient rapidly improved. He left the hospital at the end of a month without having passed the button. I have since heard that he died sometime in November from his phthisis.

The relief of the vomiting in this case was to be expected, but the total disappearance of pain was more worthy of note and indicated what may be done for irremovable gastric cancer even without pyloric obstruction. Furthermore, some thickened simple ulcers of the stomach are indistinguishable from cancer without the aid of a microscope, and for these gastrojejunostomy is curative.

Case II.—A. D., fifty years old, female servant; gave a typical history of chronic gastric ulcer, with epigastric tenderness and vomiting. The latter occurred regularly after taking food. She steadily lost ground, although under medical treatment for three weeks. Operation August 18, 1903, by the Czerny-Petersen method with a Murphy button reinforced by suture. The anastomosis was made about 3½ inches from the plica duodenojejunalis.

Liquid feeding was begun the following day. There was no vomiting and no complaint of pain. But about a week later a bad cystitis developed from catheterization. This was followed by uremia and death on August 31. Autopsy showed the anastomosis perfect but with the button in the stomach. The latter was somewhat contracted (at the time of operation its lower border reached to the umbilicus) and funnel-shaped with the fistula at the apex. No ulcer was discovered. The cause of death was a suppurative cystitis and pylonephritis. The other organs were normal.

This case was probably one of chronic gastritis, with dilatation and the constant distress and vomiting, with the consequent inability to work, and loss of flesh and strength seemed to justify the operation. At any rate, the relief was marked until uremia developed.

Case III.—M. P., forty-five years old, housewife, was sent to the hospital with a diagnosis of gastric ulcer or carcinoma. While under medical treatment and observation there was a constant complaint of epigastric pain after taking food,

and there was occasional vomiting. There had been a loss of forty pounds in weight in the past six months. There seemed to be a small tumor in the region of the pylorus. Operation September 26, revealed a cirrhotic liver and a slightly congested and thickened area, anteriorly, near the pylorus and lesser curvature. A gastrojejunostomy was performed as in the other cases, about three inches below the end of the duodenum. As the button had failed to pass in the other patients the anastomosis was accomplished by suture entirely, the gut being opened transversely around its free border to an extent equal to half the circumference. Liquid feeding was begun the next day, and the complaints ceased. The patient left the hospital at the end of three weeks, professing to be relieved, but without any noticeable gain in weight.

I have since heard that the former symptoms have returned, and believe them due to a closure of the fistula. Mayo has called attention to the need in such cases, of artificially narrowing the pylorus to prevent obliteration of the new opening. The condition of advanced cirrhosis in the liver might properly be said to have caused all the symptoms here, and to have contraindicated any operation. The propriety of the interference seemed questionable when the liver was carefully observed, but the operation had then progressed so far that it was deemed best to complete it, and the subsequent relief of the gastric symptoms while in the hospital, has justified it in my eyes. That a relapse has occurred shows the error in technic in not narrowing the pylorus. This was thought of during the operation, but the method, by suture, had taken so long (fifty minutes) and the patient was so asthenic, that the precaution was omitted.

Case IV.—A. R., twenty-eight years old, housewife; came to the medical service with a history and diagnosis of gastric ulcer. While under treatment she developed a suppurative appendicitis for which I operated in July. During and after recovery the gastric symptoms persisted. There had been an occasional hematemesis. The woman was extremely emaciated and seemed starving to death. Operation on September 27 by the Czerny-Petersen method revealed nothing abnormal in the gross appearance of the stomach, although there seemed to be a thickened area posteriorly near the fundus. But the general condition did not warrant a very careful exploration and the anastomosis was done with a Murphy button reinforced by suture as quickly as possible. The fistula was placed about 2½ inches below the beginning of the jejunum. Recovery was uneventful, liquid feeding was begun that night on account of the great asthenia, and there was a noticeable and rapid gain in strength and weight.

The vomiting ceased, and for several weeks the other complaints also. The button has not been recovered and lately some of the symptoms seem to have returned probably from contraction of the fistula as the pylorus was not narrowed and also possibly from the irritation of the stomach by the retained button.

Case V.—A. H., fifty years old, mechanic; had a Heinrich-Mikulicz pyloroplasty performed by me in December, 1902, for cicatricial stenosis. During the subsequent six months he was perfectly well and gained thirty pounds in weight. Then the obstructive symptoms began to return and on October 5, 1903, I made a gastrojejunostomy by the Czerny-Petersen method, using sutures only, and placing the fistula about 3½ inches below the end of the duodenum. As in Case III the opening in the gut was made transversely to its long axis and included one-half of the circumference of the free border. The condition of the pylorus was interesting. At the first operation nine months previously, the pyloroplasty before closing the abdomen had comfortably admitted the index finger invaginating into it the anterior wall of the greatly dilated stomach. In the second operation the pylorus was surrounded by adhesions, high up under the liver, and seemed practically closed. Recovery from the second operation was uneventful, and I found the patient at work in his shop on the eleventh day afterward. All symptoms have been completely relieved except that he tells me he has to be careful of his diet. Fermentable foods seem to cause dyspepsia, otherwise he is as well as ever. He also says that for the first few months after the first operation he had no discomfort at all and could eat anything, whereas now he has no discomfort as long as he avoids sugars, starches and cabbage. As he is an intelligent man, it seems to show that a gastroduodenostomy is preferable to gastrojejunostomy and helps to demonstrate that the former is physiologically better when possible.

If the retrocolica posterior method as described above, is impracticable, owing to adlesions or the location of the disease, then an anterocolica anterior anastomosis may have to be undertaken. For this statistics favor the loop operation with an entero-anastomosis at the base of its legs. Roux's method "en Y" with transverse section of the gut and its mesentery and implantation of the distal segment into the stomach and of the proximal into the distal lower down, is perhaps anatomically better, but involves numerous unpleasant possibilities and has not proved popular.

Whatever method is employed, and however excellent the immediate result experience has shown that gastro-enterostomy is not to be practised without good reasons. The contraction of the fistula and means for preventing it have been mentioned and the retention of the button. Peptic ulcers in the jejunum have several times been verified after death from them by perforation and hemorrhage. There has sometimes been a troublesome diarrhea of longer or shorter duration, and quite frequently an impaired digestion for fats has been noted. But the operation is universally conceded to be the only relief for benign or malignant pyloric stenosis, though not as generally accepted as it should be for painful, simple

or neoplastic ulcer. It is by all means the simplest and safest method of dealing with the repeated hemorrhages from benign ulceration, and I believe it will come into general use for much of the intractable gastric indigestion which incapacitates the patient for hard work, especially for atonic and dilated stomachs.

HOME TREATMENT OF THE TUBERCULOUS "IS JUST AS GOOD"—BUT IT IS NOT.

BY HENRY LEVIEN, M.D.,

OF NEW YORK;

PHYSICIAN-IN-CHARGE OF THE LIBERTY SANITARIUM, LIBERTY, N. Y.; MEMBER NEW YORK STATE MEDICAL ASSOCIATION; SULLIVAN COUNTY MEDICAL ASSOCIATION; MEMBER EASTERN MEDICAL SOCIETY, NEW YORK; ETC.

History repeats itself in medicine as it does in society. The feverish excitement and consequent reaction in the political and financial worlds find their counterpart in the evolution and enthusiasm of certain theories and their gradual decline and even slow death in the medical domain.

A short review of the methods or rather opinions in reference to the treatment of consumptives within the last two decades would assist us to elucidate the points we intend to discuss.

The Serum Theory.—It is within the recollection of nearly everyone of you when a number of physicians, small and big, poor and rich, left their homesteads for the Mecca—Berlin, where they would learn of the methods of administration and procure the tuberculin. It was a famous exodus. But in the height of the excitement the disciples had not followed the detailed instructions of the famous apostle. Instead of administering the serum in small and gradually increasing doses, the physicians carried off the trophy with the idea that the more the merrier: the tuberculin was given in exceedingly large quantities to the detriment of the reputation of the serum, the great discoverer, the pupils and the patients experimented upon.

Racing homeward, to be the first ones to herald the news, the expónents of this new discovery failed to be impressed by Robert Koch that this remedy is not to be administered to patients with any degree of temperature. Because of the lack of the above-mentioned accuracy—a reaction set in, the serum fell in disgrace and still more, it was pronounced dangerous. Hence the impression upon the lay mind: "no cure for consumption." And yet, quite recently, the same serum in the hands of well-known clinicians, applied in proper dosage and in appropriate cases, is reported to prove beneficial and even to possess positive curative properties.

The Climatic Treatment.—That change of climate in general, certain climates in particular and fresh air above all are beneficial in the treatment of the tuberculous was recognized in the prehistoric era. Nothing new under the sun. But theories became dominant and current that consumptives (indiscriminately) are being cured (?) when sent to high elevations. The higher the better. There hemorrhages cease, patients take on flesh in no time and get cured as by magic. Colorado and its climatic surroundings became the Mecca this time—and thousands upon thousands, incipient as well as far-advanced cases, flocked there. Taken from the East on stretchers, arriving in the Far West, a few are benefited, more are returned home in "boxes" or advised to return home, there to await the inevitable.

What hardships had those unfortunates to undergo before they reached Colorado; before they were installed in any appropriate place. What fortunes are expended (we have in mind the Eastern people and the poorer class from whose midst the mass of consumptives is recruited, and for whom a hundred dollars is probably the savings of a lifetime) and no cure, nay worse than that. Thrown among strangers, far away from home and surroundings many become homesick, many are exhausted from prolonged travel and lack of adequate accommodations on arrival, they find themselves in a worse condition than when they left their homes in the East. It takes quite a number of weeks to recuperate if they do at all. Again those with cardiac disease complicating their pulmonary affection fare badly at very high altitudes. Hence many a one who should have been advised against undertaking such a trip but should have remained at or near home, entrusting their fate to Providence—inevitably raise lamentations and also repeat, "there is no cure for consumption." Their respective physicians learning of the "results" are losing heart and faith in high altitudes. Yet there are cases upon cases known to us who merely held their own while down here, even in the mountainous regions, have done remarkably well in Colorado or in the Southwest.

Sanitarium Treatment of the Tuberculous.—The next step in the evolution and in the right direction was and is the sanitarium treatment,—sanitaria located within easy reach by the afflicted and by their respective families, located in the mountains at a moderate altitude. This idea held sway unshaken for a number of years, and greatly encouraged by clinicians and justly so supported by the medical press.

Experience has taught us by this time to be circumspect in our prognostications in any given case, not to be too optimistic as to positive and permanent cures in tuberculosis. We must bear in mind that not all cases, even under the best of treatment and surroundings, will recover. We should be elated and greatly encouraged if some good results occur, skeptical as we are (and in truth we should be) to the overwhelming reports of high percentages of cures.

The writer's experience in closely observing more than five hundred cases in his sanitarium and following up cases in private and consulting practice, also of other close-by sanitariums, is that tuberculosis is not as easily, or as speedily

and, above all, as permanently cured, as many would have us believe.

It is a melancholy statement, I confess, but it is unfortunately true, based as it is upon personal observation and close study. There may be extenuating reasons for the poor showing, but at any rate the millennium has not come as yet. It is our belief, however, that the sanitarium is the ideal place for those of the incipient as well as second stage cases.

Those of the first class have certainly justifiable expectations for full recovery, provided they are enabled to stay out long enough. Not being far away from home they are frequently visited by relations and friends, on certain occasions they might be allowed to take a short trip home, and thus break the monotony of sanitarium life,—hence no home sickness.

We will not dilate upon the benefits the tuberculous are bound to derive in a properly conducted sanitarium. We will only mention that routine and discipline are more essential to recovery than mere cheerful home surroundings. The open-air treatment which is at present universally recognized can nowhere be so satisfactorily carried out as it is in a sanitarium where each and every inmate is under direct supervision of the physician in charge, while nurses ministering to the comforts of the patients, help and urge to carry out the rules of the institution. In the treatment of tuberculosis like in that of other diseases we must often strenuously ignore all the whims and supposed inclinations. Mothers' unmasked anxieties, sisters' indulgences on one hand and shunning of the afflicted by his previous friends on the other, are not conducive to and very often miscarry the good results expected. They may kill by kindness.

Utilizing the aforesaid as a stepping stone we will alight now to the consideration of the so-called "home treatment" of tuberculosis which is by some deemed "just as good" as sanitarium treatment. Is this a new idea, and, if so, what is its underlying principle? Or is it a reaction number three? Then, we ask, after which great enthusiasm did it set in? Being aware, however, of the fact that the advocates or promoters of the idea of the "roof and fire escape" treatment of consumption as an imitation of sanitarium open-air methods have in mind only those hopelessly poor who can under no circumstances better themselves otherwise, we wish nevertheless to emphatically protest against this "new treatment," the "home treatment," which means in reality, as we will explain later, nothing more than a return to the primitive methods, but having obtained the significance of a "new treatment" will imply the casting aside of the old—the rational one.

Our nation is a reading public; no medical topic is foreign to them, and not all are capable or willing to digest the whole, and many are satisfied with headlines, and consequent dyspepsia is the result.

We wish to sound a note of warning that if this new idea shall become current and, so to say, popular, it will harm a seventh part of humanity, the consumptive, in more ways than one. "Some air is better than no air" say the benevolent savants of their new concocted doctrine, and, therefore, if the poor patient is yet in a physicial condition to climb three or four flights of stairs he is advised to ascend to the roof and stay there. He may also put a bed on the fire escape and enjoy "open-air and fresh-air treatment" up there. But foul air is bad air and is in no way fit for ventilating a septic and decomposing lung. Who are the would-be recipients of this fruitful advice? These are tenement-house dwellers, the tenements being situated in the heart of crowded districts, where myriads of microbes are floating in the air and ready to nestle themselves in the nostrils and the mouth of the person who, while sitting on the roof and believing to inflate his lungs with fresh air, inhales and swallows objectionable and deleterious parasites. The roof or the fire escape, being fifty or even one hundred feet above the ground, does not convey to our mind even a tolerable imitation of country life. To live near parks would certainly be beneficial for these consumptives who are compelled to stay in the city and at home—but how many of those poor people can afford to indulge in such luxuries—rents being so high? Again, presuming for a moment that the fire escape and the roof air should be of benefit, how much of it would the patients enjoy? We certainly want for them sunlight all the time—at least most of the time, but our earth does not pay much attention to their needs, it keeps on turning on its axis, carrying the patient, the tenement house, including roof and fire escape away from the healing sun rays, and would not linger for Mr. A., nor even for Mrs. G., for the shortest conceivable time. We must also bear in mind that the tenement house roof is common property for twenty or thirty families who use it as a drying place for their weekly laundry—and our consumptive may prove quite an unwelcome visitor up there on one hand, on the other hand the fumes emanating from the newly washed linens do not tend to improve the condition of the "lunger." The fire escape again, must be, and justly so, unencumbered for the escape of tenants in case of fire, and we should be the last ones to openly conflict with the adequate regulations of the city authorities in advising our patients to violate the law by putting a bed or an easy chair there. We may advise our patients to visit parks, but this may prove for many very fatiguing, for many physically impossible, and for a number, in the crowded districts, the parks are as thickly populated and dusty as the tenements themselves.

And who is to take care of the consumptive "at home?" This certainly devolves upon the poor wife or mother who has her hands full in caring for a number of small children and the house. Can she do it in any way approaching satisfaction?

We should not fail to mention the fact that every consumptive at any stage of his or her sickness, under the tenement-house surroundings, is positively a source of infection to immediate family and neighbors, all instructions of health boards and attending physicians notwithstanding.

We must also dwell for a while longer on the point of indulgence we mentioned before. Not to aggravate the husband, the son or the daughter, the wife or mother will often ignore the iron-clad rules laid down for the patient by the well-intentioned physician in charge, and not only miscarry the instructions but unwillingly harm their charge, no matter whether it concerns the hours our patient shall spend outdoors or the quantity and quality of food he or she is allowed or prohibited to indulge in. From our actual experience in maintaining tuberculosis patients in our sanitarium we have convinced ourselves that they are capricious, irritable and selfish in their relations towards the immediate family. They are the greatest tormentors of the family; not being conscious of the extent of their ailments and ever hopeful of speedy recovery they are very impatient and never satisfied with what is done for them. Naturally the family will exert itself in every way to allay irritability.

In this connection and as a means of illustration I will briefly record two cases, whose histories will bear directly upon the points under consideration:

Case I.—Miss L., nineteen years old, one of eight children; "shopgirl" by trade. Father an elderly man, working hard to support family. This girl entered sanitarium in August, 1902. Physical examination revealed consolidation in right upper lobe anteriorly and posteriorly. Stage active. Considerable P.M. temperature. She coughs a good deal with much expectoration; lost during the summer more than 20 pounds in weight. Has night sweats. Appetite poor. Very weak. She remained under our care nearly four months. She has improved considerably both objectively and subjectively. Her temperature was about normal, she ceased to cough, felt a good deal stronger, was able to take long walks and rides without fatigue. Her local condition also showed improvement proportionately. Though the consolidated area did not resolve but there were justifiable hopes of having the disease arrested. She begged to be allowed to go home for the winter months to return in the early spring. For her benefit her parents moved from the crowded district, where she contracted the disease, to a more quiet and refined neighborhood, their house facing one of the small city parks. Believing, as we did, that the months of December, January and February, the cold winter months, would at least not retard her gained health, if not helping her along in the way of further improvement and instructing her to live in the park, to eat there, etc., I permitted her to go home. While in the city, sometime in January that year, I went to the park in the hope of finding this girl and other patients (who left the sanitarium about the same time, and who were living in the same neighborhood) there. It was a fine cold and sunny morning. To my chagrin I found none of my patients there. I called at the girl's home and found her in bed in a darkened room, though with windows facing the park. It was nearly 11 A.M. Her mother told me she did wake her and tried to persuade her to go out in the air, but she would not, "she was so tired and lazy and wanted to rest." The mother, of course, gave in.

Her appetite was again capricious and poor, and she was losing the weight she gained while in Liberty. Sometime in February, while in the city, I was asked to see her and was grieved to find that the active stage made its appearance again and disintegration of the lung had set in. They wanted my opinion as to the possibility of removing her to the sanitarium again, and I concurred with the sense of the attending physician that this move might prove fatal and advised rest in bed and await developments.

By the end of May her fever had somewhat abated, and reluctantly I have readmitted her to the sanitarium. A large suppurating cavity developed in the interim and she was in a very weak condition. Though her subjective symptoms improved somewhat, she continued to lose flesh, the cavity enlarging. She continued fairly well till October when cardiac debility made itself manifest, when I insisted upon taking her home where, in a few weeks, came the final solution.

This case illustrates fully how much harm motherly indulgence or lack of rigid discipline has done to this girl. There was plenty of nourishment, mother's care, physician's attendance and stringent instructions both by the attending physician and myself. Why such a decline and return to the worse? The change of air has undoubtedly contributed its share, but the unenforced sanitarium rules had done the most.

Case II.—Mrs. M. B., thirty-one years old; fourteen years married; three children. Youngest child five years old. Family history negative. Entered sanitarium August 12, 1902. Eight months before she started to cough. She thought she might have become infected by whooping cough from her child. Has had six attacks of hemoptysis—never to any considerable extent. Much expectoration, no pain, but only a sense of burning on the left side. No night-sweats. Lost somewhat in weight. Anemic. Temperature at 4 P.M. 99.5° F., pulse 80, weight 135 pounds. Inspection showed a fairly nourished body with slight recession on right side. Auscultation revealed consolidated area right middle lobe anteriorly and posteriorly. She too continued improving while in the sanitarium. On November 23 the following entry was made:

"Though consolidation still marked, yet there are no râles on the right lung. Left lung clear, but suspicious area posteriorly. Weight 145 pounds (gain of 10 pounds within fourteen weeks)." By this time she too had made up her

mind to go to the city. Her family lived in the Eightieth streets, having two parks at her disposal. She would certainly take good care of herself, follow strictly sanitarium régime, and I did not oppose it, as in the former case. I saw her twice during the winter months (December 1 to March 1). She seemed to hold her ground well, the only change toward the worse was that she coughed slightly more than she did while up in Liberty, but as she intended to come out in the early spring again I did not entertain any apprehensions. But she did not come out and instead lingered at home, engaged her time in light housework and care of the children and by and by fell into the old habits, ignoring all instructions and precautions. She gradually became so weak as not to be able to walk out into the air, even if she wished to do so. I did not hear from her until July 27 last, when she was brought to the sanitarium by her sister from Troy, N. Y., whither she had gone for a change of air. Her condition was appalling; pale, emaciated, pulse hardly perceptible, could not walk without assistance. She lost 30 pounds in weight. A large cavity had formed at the place where the consolidated but seemingly cicatrizing area had existed. The left lung was in catarrhal condition with high P.M. temperature. During her six weeks' stay, under the best of care and attention, she had made no progress, she was losing weight, taking little nourishment. A catarrhal laryngitis set in as a complication in the middle of September, which did not yield to treatment. Seeing the decline, I advised her to go home, as I could entertain no hope for improvement. I saw her recently with their family physician; she is going speedily down hill. Her hoarseness did not leave her; apparently a tuberculous ladyngitis developed. My prognosis was very unfavorable and had the painful mission to so inform her husband. Now, this woman was old and sensible enough to care for herself; she had the necessary means to supply her wants, but there was nobody to urge her in doing her full duty to herself and she relapsed and badly so.

The two cases cited will suffice in demonstrating how inadequate is the so-called "home treatment," even for those who have learned of the systematic ways in an institution.

The question may naturally arise, what are we to do with the unfortunate army of the poor who can't afford country life and have no means of entering special sanitariums? In answer, would say that there are contingencies and incidents in society and communities at large which somebody has to cope with, and therein lies our protest against popularizing the idea of "home treatment." Our contention is, what the nation, individual States, municipalities, philanthropists and private enterprise do with regard to other diseases (yellow fever, smallpox, diphtheria, typhoid fever, fractured bones, fibrous uteri, etc.) will do or will have to do, and in the most advantageous manner, in reference to the poor tuberculous.

Our Federal Government has established special sanitaria for the treatment of the consumptives discovered in the ranks of the Army and Navy. These sanitaria are located in the most desirable quarters, under the best of surroundings, and most gratifying results are reported.

Are not citizens at large entitled to the same consideration in the hands of their respective States and Cities? With the idea of the "new treatment" the "home treatment," before the public, our consumptives will be left to their fate or depend upon the support of kind-hearted neighbors or upon city charities—all this may bring temporary relief, but would never lead to ultimate results.

On the other hand, being impressed by the family physician, by consultants, by both medical and lay press, that only country, or better still, sanitarium life can offer a fair chance of patients' recovery, the immediate family and relatives will strain their resources to supply the necessary funds for a longer or shorter time. The public's demand for help in this direction will arouse the respective governments from apathy; philanthropists will direct their munificence into this channel, private enterprise will not linger long behind and this great want will be satisfied. Why, we have so many hospitals (State, city, of private charity, private hospitals) and so few sanitaria—and the need of them is so great! But with the idea that "home treatment" is "just as good" all efforts will be relaxed and the poor consumptives will become the innocent victims hereby.

Summary.—It is our duty to have the public at large impressed with the importance of fresh air, nourishing food and, above all, rigid supervision by physicians and nurses. These ends may be best attained by establishing sanitaria in sufficient numbers to supply the demand, and that "home treatment" as a "treatment" is not only a step backward and is meaningless, but it may prove a menace to consumptives and mislead the public mind into believing it to be a "new treatment"—and therefore this term should not appear upon the pages of our medical press.

I am pleased to report that since the above was written great efforts are being exerted in behalf of the consumptive poor, both as to prevention and cure, under the able supervision and enthusiastic management of our new Health Commissioner and medical officer, Dr. Hermann Biggs. The Riverside Sanatorium is enlarged and better accommodations are afforded the inmates.

Sites are being looked and "appropriations" hoped for the establishment of an out of town Sanatorium in the Orange or Sullivan County mountains for the treatment of incipient tuberculous cases.

Special classes for the treatment of the tuberculous are being established in connection with the city dispensaries under the supervision of physicians trained for this purpose. Trained nurses are attached to these classes, who visit

those ambulatory cases at their homes, ministering to their needs and supplying them, in case of need, with material help from special funds. From the materials of these special classes patients will be assorted and sent to the respective municipal Sanatoria. Stringent and vigorous measures are taken to suppress the spitting nuisance. The New York State Sanatorium is expected to open its doors in the coming midsummer. And so we are moving on.

1847 Madison Avenue.

THE IMPORTANCE OF DROPSY AS A SYMPTOM.*

BY A. C. MORGAN, M.D.,
OF PHILADELPHIA.

The term "dropsy" is a shortening of the word "Hydropisie," meaning "watery appearance." It is applied to the presence of an *abnormal* amount of watery fluid transuded from the blood vessels or channels into the cellular tissues and lymph spaces (Gould).

The term "edema" (to swell), is used when there is a moderate surplus of water in the tissues; when excessive, it is termed "anasarca" (through the flesh), and if the serous cavities are also the seat of the transudate the condition is called "general dropsy," or the prefix "hydro-" may be attached to the cavity or part affected.

An abnormal quantity of fluid in a cavity, when unaccompanied by fever, is called a *transudate;* when due to inflammation, as indicated by fever and other symptoms of inflammation it is then called an *exudate.*

Edema or dropsy may be unilateral, bilateral, local or general. When unilateral, or local, the cause is to be found in the immediate proximity, and it always produces obstruction to the *return* circulation. When bilateral it may be due to the rare condition of a point of obstruction at corresponding parts of the two sides affected, as, for instance, thrombosis of both femorals may produce a bilateral symmetrical edema of the legs. It is the rule, however, in bilateral or general edema to find a central cause, either in the heart, kidneys, liver, lungs or blood.

The cause of *local* edema is: mechanical pressure upon the capillaries, veins or lymph spaces. It may be acute, as from an abscess: subacute, as from a rapidly growing tumor; chronic, as from lymphangitis, after operations or fracture of bones, with inclusion of some veins in the scar tissue surrounding the site of the lesion, or imperfect apposition of the parts and consequent failure to establish collateral circulation; following a phlebitis, especially of the femoral; neoplasms of any kind, particularly those affecting the lymphatic glands as these are located in chains in the flexures of the body, as in the axilla or groin, and always in close relation to the veins.

Section of a nerve, for example, the sciatic, will paralyze the arteries supplying the part, causing dilatation of the arteries and capillaries and a pouring out of more blood than the lymphatics and veins can care for, with resulting stasis and fluid accumulation (Quain).

The cause of local edema in abscess is from arterial dilatation, due to the excessive amount of blood present, as well as to the mechanical pressure offered by the pus which forms and permeates the tissues.

An important point often overlooked by the physican is the occurrence of edema of the ankles as a result of, or part of, anemia, and this condition is usually accompanied by a slight fever, irregular in type, seldom going beyond 101° or 102° F. It may simulate, or, in fact, be partly the cause of the slight fever noticed in incipient phthisis. After a severe attack of typhoid fever or other long continued toxemia, the low fever and slight malleolar dropsy that baffle all efforts to overcome may respond to a vigorous course of hematinics.

This malleolar dropsy in anemia is chiefly due to an altered composition of the blood caused by the primary disease, as in Bright's, pernicious anemia, intestinal toxemia, chronic dysentery, scurvy or any cachexia. The solid elements of the blood are here decreased, the column of blood in the vessels losing its "body," permitting a backward flow, or at least inhibiting the forward flow and putting increased work on the heart; it, in turn, being illy nourished by the poor quality and quantity of blood supplied, now acts less strongly, diminishing the *vis a tergo* and the column of blood still further stagnates, increasing the ankle edema. The tonus of the capillaries, being also lessened, adds to the condition, permitting a transudation of serum.

The skin in a *transudate* is cold, symmetrically swollen, pale, shiny and smooth, pitting on pressure and slowly resuming its former shape, or showing marks of clothing, shoes, etc., and painful only from the distention of the tissues. If the tissues are greatly distended for a considerable time there may be a rupture of the epithelium, permitting oozing of beads of clear fluid, not containing blood.

The skin in an *exudate* is hot, non-symmetrical, red, pitting on pressure which quickly disappears after the pressure is removed and constantly painful,—throbbing in character, and the skin breaks only when the abscess points, the exudate being constantly mixed with blood.

Edema of the skin, in contradistinction to a bulging, is important, in that it tells us that the fluid contents that before were non-septic, are now septic. Thus, in pleurisy with effusion there is bulging, but in empyema there is bulging *and* edema; in hydronephrosis there is bulging, but in abscess of the kidney there is bulging *and* edema; as also in an enlarged liver there is bulging but when this enlargement is due to an abscess of that viscus there is also edema of the chest wall.

Edema of the neck, including the upper thorax, or of the arm, also including the upper thorax, may be caused by aneurism or mediastinal

* Read before the Northwest Medical Society of Philadelphia, December, 1903.

growths, being gradual in onset and permanent in duration. Hydrothorax, when local, may be due to these causes, or to an enlarged right auricle pressing on the vena cava. Bilateral hydrothorax is always a part of a general dropsy. As a symptom, dropsy must always be given its full importance, for diagnosis, prognosis and treatment. It must always be considered as a pathological condition, and one which will not right itself without proper medical or surgical attention.

As a general rule, this triad can be accepted: (1) Initial dropsy of Bright's appears as edema under the lower eyelids, seen upon arising in the morning, disappearing by night; (2) in valvular heart disease, myocarditis, lung or blood conditions its first appearance is in the ankles, appearing late in the day and increasing toward night and, (3) hydroperitoneum or ascites is the first dropsy due to failure of compensation in the portal circulation, as in cirrhosis of the liver.

The local edema resulting from a small abscess is slight in importance but becomes increased in value in edema of the chest wall as indicating empyema. A slight local edema of the leg due to a lipoma pressing upon the femoral vein is as nothing compared with the edema occurring as the result of thrombosis on the same site. The onset of slight malleolar edema in emphysema tells us that the conservative development of hypertrophy of the right ventricle which coexisted has now begun to fail and that degenerative changes have advanced to a dangerous degree.

The early edema of valvular heart disease, seen in the ankles indicates also the gradual weakening of the right ventricle,—that stronghold of support in all forms of valvular heart disease,—due to fatty degeneration of the muscle. This may be present for years and not advance much until some sudden strain or intercurrent disease as bronchitis, grip or bronchopneumonia overcomes all the reserve force and the patient dies from sudden pulmonary edema.

Just so soon as we notice commencing ankle edema in heart conditions should we institute measures to check its advance,—nay, more, we should already have used our prophylactic measures to have deferred the onset of this condition.

General dropsy or anasarca, due to Bright's,—acute or chronic—or heart disease, may be recovered from if the patient be in the prime of life, possessed of good in preference to fatty muscle and the poison or factor that has caused the condition be entirely removed. A patient, however, who has once been the subject of general dropsy, regardless of the cause, is in imminent danger of a recurrence and a fatal termination.

When dropsy ensues during the course of any cachectic conditions, as tuberculosis, cancer, chronic malarial cachexia, pernicious anemia, etc., it can be inferred that the patient is nearing the last stage of the disease, the toxemia having produced the high degree of anemia present, and unless he respond to treatment, as in malaria, or have a remission in the condition as is seen in pernicious anemia, the end is not far off.

Edema of a part, after fracture or operation, is a sure indication of need of attention on our part to establish the return circulation or to remove some cause of the obstruction that is present, and this is usually best done by massage and electricity. Hydrothorax, or a pleuritic effusion, even if only moderate, must be constantly treated, medically or surgically.

This dictum may be given: Dropsy *is* an important symptom and the cause must always be sought for and removed.

So long as the effect is present the cause has not been removed and it demands intervention for the reason that the cause will become progressively active and the patient die, directly or indirectly, as the result of our lack of appreciation of this early warning. "A stitch in time saves nine."

MEDICAL PROGRESS.

MEDICINE.

Immunization against Tuberculosis.—Since the cure of tuberculosis by means of bacterial products is still a dream of the future, several attempts have been made to immunize at an early age and a great future was promised for Behring's plan of feeding infants with the milk of cows which had been treated with germs of human tuberculosis. The weak point of the method, however, lies in the fact that the milk must be employed uncooked so that the addition of formalin as preservative will be necessary. More recently Friedman has discovered that the germ causing tuberculosis in the turtle is very similar to the human germ, but absolutely innocuous even to small mammals. The injection of a large amount causes a slight febrile reaction but the animals increase in weight and if killed after months, are free from tubercles. If human bacilli are injected later, the animals remain well. Inversely, turtles may be immunized in the same way with the germs of mammals. The experiments of Moeller are based upon the same principle. According to A. Gottstein (Therap. Monatshefte, Feb., 1904) practical results are more liable to follow the method of Friedman than that of Behring.

The Relations between the Activity of Skin and Kidneys.—The value of diaphoretic treatment in diseases of the kidney has been made the subject of experiment by E. Bendix (Deut. med. Woch., Feb. 18, 1904). He found it impossible to influence the normal freezing point of blood by the most energetic sweating procedures. It was also found that by withdrawing the water, no thickening resulted, nor did any reduction in the molecular concentration take place by the elimination in the sweat of substances dissolved in it. Both normal animals and those with kidney affections showed the same results. Observations of a similar character were also made on patients with nephritis who were treated by diaphoresis and venesection and the results were about the same as those seen in animals. When the freezing point was normal, no changes were noted after diaphoretic measures had been instituted. When the freezing point of the blood was low, however, as in chronic nephritis, the sweating raised the freezing point to almost the normal figures. The author suggests as an explanation that reserve supplies of water must be stored in the body which serve to wash out solid materials in case of necessity. In acute uremia particularly, it was found that more solid substances

were eliminated in the sweat under these circumstances than when the freezing point of the blood was about near the normal. The work shows the advisability of energetic sweating procedures in renal insufficiency as a means of restoring the freezing point of the blood to the normal figures.

The Effect of Mountain and Sea Climate on Man.—A study of this subject has been made by A. Lowy (Deut. med. Woch., Feb. 4, 1904), who finds that the test of the electrical conditions give the same results in each and the effects on the metabolism of the body are approximately the same. In high altitudes the rarity of the air is probably a minor factor, the benefits being mainly the result of the purity of the air, its constant motion and the abrupt changes from warm to cold. All of these, however, may be found at the seashore. The indications for either one or the other should be carefully examined. Where overexcitement or overstimulation is already present the patient should not be sent either to the seashore or the mountains. These places are only for those who are possessed of a reserve energy. It is not definitely known whether the climate at the seashore has the same effect on the blood as that of the mountains. He believes in the possibility, but thinks that further research is necessary to elaborate the details.

Treatment of Pyloric Stenosis with Thiosinamine.—A case in which this drug was used as a last resort, when operation had been refused, is reported by A. Hartz (Deut. med. Woch., Feb. 25, 1904). The patient, a man of fifty-six years, had been suffering from a benign stenosis of the pyloris for thirteen years. One-half a Pravaz syringeful (=½ dr.?) of a 15-per-cent. solution of thiosinamine in alcohol was injected into the back. The symptoms began to improve and in about three months, after the thirteenth injection, the man was eating ordinary food without inconvenience. During five months he was given twenty-three injections, and was apparently cured. The reaction to the drug was marked by headache and depression in only a few instances during the early treatment. Later no unpleasant reaction followed.

Olive Oil in the Treatment of Chronic Dysentery.—The success of this treatment in chronic gall-stone disease, led to its employment in chronic dysentery and enterocolitis of tropical origin, by H. H. Rutherford (Am. Med., March 12, 1904). He bases his suggestion on the analogy of these two conditions, which may seem far-fetched, but on closer consideration it is found that in chronic gall-stone disease there is frequently a hypertrophy of the liver, while in chronic dysentery there is usually a hyperemia or atrophy of the same organ. Other pathological conditions common to both diseases are also present and are due to practically the same set of causes, gastro-intestinal fermentation and absorption of the putrefaction products in the liver. About 75 cases of intractable tropical dysentery were treated about as follows: The olive oil must be pure and the author prefers that produced with especial care in California. During the first period the patient is given 30 c.c. of oil t.i.d., which is increased to 60 c.c. q.i.d. at the end of the first six days. At first nothing but milk is given, followed later by scraped beef and eggs. During the second period 90 c.c. is given three times daily, until convalescence is established and the patient regains his full weight, which may take from one to two months. During the third period the patient is allowed to get up, restored to a full diet and the oil is gradually decreased until recurrences are no longer liable. The oil may best be given at first with equal quantities of hot milk on an empty stomach about an hour before meals.

SURGERY.

Movable Kidney.—The present practice, in this condition, is not to interfere until compelled to do so by torsion of the pedicle, or some serious pathological condition. While it may be conceded that only a small percentage of patients suffering from movable kidney have obstruction of the ureter, necessitating an operation for relief, Rufus B. Hall (Am. Jour. of Obst., Jan., 1904) believes that quite a large proportion develop hydro- or pyonephrosis, and in a few, complete obstruction. Many of these cases suffer more or less discomfort in the region of the displaced kidney. The pain, which is of a burning, dragging character, is not severe enough to necessitate an anodyne, yet is a source of great discomfort and annoyance. The pain is often constant so long as the patient is in the upright position, but is very frequently relieved by a recumbent position. Fixation gives these patients relief. The author is of the opinion that these cases should be operated upon before a hydronephrosis may develop, as the gradually increasing curvature of the ureter with its obstruction has a marked effect upon the excretory function of the kidney and may even eventually produce atrophy and cystic degeneration. The urine being unable to escape, it distends the pelvis and calices, causing destruction of the tubules and the Malpighian tufts, and terminates in a cyst, the walls of which are composed of the pelvis and the capsule of the kidney. During the acute attacks, the examination of the urine will reveal more or less pus present; but this will almost entirely disappear three or four days after the attack has subsided. Thus examination of the urine between attacks may cause a faulty diagnosis. The operation of relief of this condition, is almost devoid of danger; and, if it is performed before serious pathological changes have taken place in the organ, relief is immediate and permanent.

A Complicated Case.—A rare and interesting case is reported by T. L. Coley (Medicine, March, 1904), of which the chief features are as follows: The patient, a man of thirty-three years, suffered from a stricture of the cardiac end of the esophagus below the diaphragm. This was the result of a corrosive esophagitis of a phlegmonous type and led to the formation of a subdiaphragmatic abscess. This communicated subsequently with the left pleura, producing an extensive empyema, which was loculated and separated the lobes of the lung. There was finally a terminal purulent peritonitis. The range of temperature and the result of the leucocyte count were atypical, which may be explained as the result of two processes,—the profound toxemia and the prolonged starvation from which the patient suffered. A number of cases have been reported of abscess following an infection from the esophagus, but the author believes that this is the only case where a subdiaphragmatic abscess was formed which subsequently ruptured into the pleura and also caused in addition a purulent peritonitis. The infection of the pleura seemed to have taken place through the lymphatics rather than to a rupture through the diaphragm, for the classical symptoms of this condition, sudden cough, extremely rapid respiration, profuse expectoration and collapse, were all wanting and the autopsy did not reveal the cause of the extension.

Substitute for Rubber Gloves.—An interesting method, which has been put to the test of practical experience, is suggested by J. B. Murphy (Jour. Am. Med. Ass'n, March 19, 1904). He has found that a solution of gutta percha in benzine or acetone meets all the requirements of rubber gloves or the adhesive rubber dam. A solution in benzine (4 per cent.) is best for the hands and the author's technic is as follows: The hands are first scrubbed with green soap

and hot water for five to seven minutes, then washed for three minutes in alcohol, after they are thoroughly dried the rubber solution is poured on and allowed to dry without rubbing after the entire surface has been covered. The latter takes about two to three minutes and then the hands may be scrubbed in soap and water between operations, or washed with any of the antiseptic solutions. The coating will wear off the finger tips if the operations are many or prolonged, when another application may be made. The abdomen may be similarly covered before operation, but the acetone solution is preferred, as it dries in a few seconds. Murphy states that the advantages of this method are evident. There is no perspiration from the coated surface and where it wears off there is no accumulation of epithelium or secretion beneath. It is entirely impermeable and can be readily removed by washing the hands in benzine, the skin being unaffected and remaining soft and smooth.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Agglutination Phenomena of the Staphylococci.—A contribution to this subject has lately been made by KLOPSTOCK and BOCKENHEIMER (Deut. Arch. f. klin. Chir., Vol. 72, No. 2), which is of considerable theoretical and practical value. They have attempted to show that by means of agglutination methods it may be possible to differentiate among the large number of staphylococci occurring in the air, the normal skin and healthy mucous membranes, those of a saprophytic from those of a pathogenic nature, and the conditions which may influence the production of either class. By means of cultural and immunization experiments they found that a serum derived from pathogenic cocci agglutinates not only the homologous variety but also the larger number of the other pathogenic varieties. Pathogenic staphylococci which are agglutinated by a specific serum only slightly more than by the normal serum of the same animal, are able to produce a serum which shows marked agglutinating properties not only toward the same, but also toward other varieties of pathogenic staphylococci. Saprophytic cocci are not agglutinated by a serum which is derived from pathogenic staphylococci. A serum may be produced from saprophytic staphylococci which will agglutinate other saprophytic but never pathogenic varieties when well diluted. There are, moreover, certain saprophytic staphylococci, from which it is impossible to produce a serum with agglutinating properties. The authors believe that these agglutination tests form a practical means of differentiating the pathogenic from the saprophytic staphylococci. As regards the formation of hemolysins, it was also found that only those varieties of cocci were capable of producing hemolysins which had been determined by the agglutination tests to be pathogenic in character.

Observations on Human Bile.—While the bile of animals has been very carefully investigated, few articles on human bile in various diseases, may be found in literature. T. KIMURA (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) states that very marked variations in physical and chemical properties may occur. Thus in tuberculosis the amounts of pigment are very often low, while in congestive conditions, especially in diseases of the heart, a much darker fluid is excreted, probably since more red blood cells are disintegrated in the liver. The specific gravity varies between 1.012 and 1.04, the dry residue between 2.68 and 20.63 per cent, and the viscosity between 1.46 and 58.24. In obstructions in the common duct, the amount of pigment, dry residue and viscosity are considerably increased. Urobilinogen is found generally, urobilin less often, but in the newly-born, in marked diarrhea and where no communication exists between the biliary and intestinal systems, both substances are absent, since they are most likely of enteric origin. The normal feces also contain urobilinogen except in obstruction of the common duct.

Serodiagnosis for Identifying Blood.—The serodiagnostic method for identifying blood of man and different animals must be regarded as a most valuable procedure in legal medicine, provided the examiner is thoroughly versed in the technic. To obtain a serum which precipitates human blood G. HAUSER (Münch med. Woch., Feb. 16, 1904) first injected placental and retroplacental blood into rabbits, but later obtained equally good results with the serum of cadavers, introduced intraperitoneally or subcutaneously twice a week in amounts of 15 to 20 c.cm. Even the serum of septic bodies remained sterile and was well borne by animals, but the blood from tuberculous cases should be avoided. If the injections are repeated too rapidly, a very potent serum will be obtained, but this will also precipitate the blood of other species; it is thus advisable to test each serum with different varieties of blood kept in stock. In legal cases a serum should be employed which, if added to human blood in a proportion of 1:30, gives rise to a turbidity, soon to be followed by a flocculent precipitate, if kept in the incubator for half an hour. Where only small quantities of blood are available for examination, capillary tubes may be used. The blood-extract is first allowed to flow in by capillary attraction, then the necessary amount of serum is sucked in and the tube sealed and set aside. If the test is positive, a ring-shaped turbidity will appear at the line of contact of the two fluids which will gradually extend along the tube. Thus performed the test is much more accurate than with the older methods. Serodiagnosis is not always necessary, for occasionally a simple microscopical examination will suffice to determine that a blood is not human, as where only nucleated red cells are found.

Notes on Blood-coagulation.—There is no longer any doubt that the blood platelets play a most important part in the coagulation of blood, for P. MORAWITZ (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) has succeeded in isolating them from the other elements in the blood and has been able to determine that they contain a large amount of thrombogen. The other cells lack this substance, so that there is every reason to believe that the platelets are not derived from the disintegration of erythrocytes or leucocytes, but form an independent group. A small amount of thrombokinase may also be detected, but the bulk of this substance comes from the leucocytes. In extravascular clotting, small nodules often form along the walls of the vessel just prior to clotting; these consist almost entirely of platelets. The number of platelets in the blood also seems to stand in some relation to the rapidity of coagulation. Further experiments are in progress to determine if thrombogen and thrombokinase may be employed therapeutically, perhaps in conjunction with adrenalin in severe hemorrhage. One great difficulty lies in the fact that kinase is an extremely labile body, but a permanent preparation may be obtained by evaporating and drying in vacuum. By dissolving in water shortly before use, a very potent solution results.

Vincent's Angina.—The peculiar membrane and ulcerations in the throat characteristic of Vincent's angina, seem to be due to a long, spindle-shaped bacillus with slight mobility and numerous lighter areas in its body, and an actively motile spirillum, since both generally occur in pure culture upon the surface. The bacillus has also been found in other lesions, as in a sublingual abscess, submaxillary adenitis, in the pus of

empyema and in hospital gangrene. It may even be found in the mouth in conditions of perfect health. Clinically the disease is very mild, with only slight fever and moderate swelling of the glands, but there are cases on record complicated by polymorphous exanthemata, synovial effusions and pleuritis, probably due to secondary infection. Not rarely a stomatitis goes hand in hand with the angina. Locally two forms may be recognized: in one, a tonsil is covered by a grayish-white membrane which leaves a superficial raw surface when cast off; in the second the membrane is thinner but the ulceration deeper. In the great majority of cases the affection is unilateral and smoking seems to be an important etiological factor. The differential diagnosis is occasionally difficult, since the ulcers may closely simulate diphtheria or primary or secondary syphilis. What complicates matters, is that the germs in question may occasionally grow upon these ulcerations as harmless saprophytes, but they are then generally mixed with other organisms. All attempts at cultivation have hitherto been unsuccessful, though if contaminated with other bacteria, it is sometimes possible to obtain a growth on serum media for two generations. A. Gross (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) has had occasion to examine the infiltrated tissues microscopically; he found the inflammation fibrinous in character, with many bacilli, almost in pure culture in the superficial layers and a much smaller number in the deeper tissues. Spirilla were also found but are of less importance, since abundant on healthy mucous membrane. Though the chain of evidence is not complete, there is every reason to believe that the bacilli are the cause of the ulcers.

NEUROLOGY AND PSYCHIATRY.

Micropsia and Macropsia.—The word "micropsia," according to O. Veraguth (Deut. Zeitsch. f. Nervenheilk., Nov. 10, 1903) signifies a qualitative disturbance of sight, in which the individual sees things lying in his field of vision smaller or farther removed than they really are. Macropsia or megalopsia is the opposite condition. Both phenomena appear in various diseases of the nervous system. Five cases were reported by Charcot; they were tabes complicated with hysteria, traumatic hysteroneurasthenia, tabes and hysteria in which there was monocular micropsia and polyopsia, hysterical degeneration, and a case marked by hysterical crises. Various authors have recognized these conditions among the aura of epilepsy. The author reports four cases as follows: (1) In a case of undoubted epilepsy, macropsia occurred as a phenomenon of petit mal. (2) A case, probably of nuclear origin, of metasyphilitic type or associated with nutritive disturbances in the medulla as the result of arteriosclerosis, presented micro- and macropsia associated with dyschromatopsia. (3) A case of typical hysteria presented a monocular micropsia and dyschromatopsia and followed by temporary amblyopia. (4) A patient in whom an occasional micropia associated with abnormal sensations of movement appeared, was an example of a neurosis of exhaustion with hereditary taint. In concluding, the author finds that micropsia and macropsia occur in hysteria, epileptic aura, petit mal, psychoses exhaustion of nervous energy (neurasthenia), tic convulsif and probably in organic diseases of the nuclei of the motor nerves of the eyeball. These symptoms are of no pathognomonic value. They may be isolated or associated with other disturbances of vision and may be localized in one eye.

Abdominal Symptom-complex in Diseases of the Lower Part of the Dorsal Cord.—The increasing importance of abdominal pain as a significant symptom in local and remote pathological conditions, imparts a peculiar value to the observations on the above subject by H. Oppenheim (Deut. Zeitsch. f. Nervenheilk., Nov. 10, 1903). Diseases of the lower part of the dorsal cord between the levels of the eighth and twelfth dorsal roots produce a charactertistic complex of root and cord symptoms. This is particularly typical in affections that gradually develop and that encroach upon the cord from the outside, as in the case of neoplasms. In these cases there are found unilateral pain following the distribution of the nerve-roots, diminished or totally absent reflexes in the domain of the abdominal musculature of the corresponding side, degenerative paresis of the muscles, paresthesia or anesthesia in the areas of the distribution of the eighth and ninth, or tenth and eleventh or of all four roots. In Brown-Séquard's symptom-complex pain and disturbances of reflexes precede the other symptoms, but this order is not a constant one. In most cases of this disease thermo-anesthesia of the opposite side is the first manifestation, still it is sometimes preceded by homolateral spasm or paralysis. Also characteristic is the transition from the hemilateral to the bilateral symptom-complex (girdle-sensation) bilateral areflexia, anesthesia paralysis, meteorism, paraplegia, etc. One must be cautious in making the diagnosis of a local condition from these symptoms. Simple or spastic non-atrophic paralysis of the abdominal muscles may be produced by conditions higher up in the cord. Moreover, in the healthy and in cases of intra-abdominal disease, there may sometimes be found differences in bone and muscular strength between both sides of the abdomen. The abdominal reflexes, moreover, are inconstant ones, their failure even not necessarily indicating a pathological condition. These reflexes are frequently affected in cases of intercosto-abdominal neuralgia and neuralgias of the viscera.

Case of Hystero-epileptic Chorea.—For more than a century articular rheumatism has been held to be a cause of chorea minor, says Giovanni Morelli (Gazz. degli osped., Feb. 21, 1904). In 1887 various forms of streptococci were found in three cases of polyarticular rheumatism. Many experimentors have found proof of an infection. Since then many writers have claimed the infective origin of chorea, and articular rheumatism accompanying or preceding chorea is generally admitted. Sydenham's chorea has been observed following many other infectious diseases not associated with rheumatism. Chorea develops suddenly after violent emotions, trauma, syphilis and in cerebral lesions. It is not rare in pregnancy. Rheumatism may be only one of many causes. Heredity is of the greatest importance. Every age of life has its own peculiar diseases. In infancy and the period of early development, eclampsia, epilepsy, infantile paralysis, chorea, and certain other nervous diseases are seen. This is due to the physiology of the brain, which from the period of birth to puberty is changing and in a condition rendering it liable to various disturbances. The writer reports a case of a boy suffering from chorea with heredity, age and previous rheumatic infection, the muscular contractions affecting the face, neck, tongue, limbs, pharynx and heart. Muscular fatigue did not appear as in ordinary chorea. Abolition of the pharyngeal reflex, cutaneous hyperesthesia and dermographia suggested hysteria; in addition increased reflexes, painful areas in abdomen and back, easy suggestibility, and the quieting of the tremor under the influence of a command still further demonstrated hysteria. In addition to these symptoms, a form of epilepsy was present, of the ambulatory type, automatism, amnesia, and occasional convulsions. Mentally the patient was depressed, and at times suicidal. The

conclusion drawn from a study of this case is that a marked affinity exists between epilepsy, hysteria and chorea.

A Few Remarks upon Stuttering.—Although stammering has been regarded as almost always a manifestation of some neurosis, yet, according to O. Maas (Deut. Zeitsch. f. Nervenheilk., Nov. 10, 1903) in a greater proportion of cases than yet realized, it is in all probability to be attributed to local organic changes in the central nervous system and even in the peripheral nerves. The symptoms of organic stuttering are not yet well understood. Possibly deviation of the tongue will turn out to be one, and possibly symptoms will be found in the area of distribution of the facial nerve.

PHYSIOLOGY.

A Study of the Antagonistic Action of Poisons.—A contribution to this subject has been made by T. Sollman (Am. Jour. of Physiol., Feb. 1, 1904) in studying the simultaneous action of pilocarpine and atropine in the developing embryos of the sea-urchin and starfish. A. P. Matthews had found that the development of the latter is hastened by pilocarpine and retarded by atropine. The advantage of studying the effect of the simultaneous action of the two drugs in these simple organisms in which the effect is a plain one and can be easily observed, is apparent. The author found that while small doses of pilocarpine hasten the developments of the embryos, larger doses or a prolongation of the action, produce the opposite result. Small doses of atropine have no effect, but larger doses hinder development. When both drugs are used, there may be antagonism or synergism, according to the conditions; but the depressant action always tends to predominate. The observed resultant is always below the mathematical average. Even with the best antagonism, both poisons are producing their action, as shown, for instance, by the greater liability of the protoplasm to depression. Stimulation can be readily and completely removed by very small doses of a depressant (even by doses which are inactive when used alone). Depression is lessened by only a limited range of doses of the stimulant. Its removal is in no case complete. This gives to stimulation a limited but distinct usefulness. The optimum dose of the stimulant is smaller when the embryos are depressed than when they are normal. Larger doses are synergistic to the depressant, and hence harmful. The dose of the stimulant must therefore be chosen smaller, when depression exists, than in normal specimens.

The Action of Radium Rays.—A series of chemico-physiological experiments were performed by G. Schwarz (Pflüger's Archiv, Dec. 17, 1903) on hen's eggs, with the view of elucidating some of the important problems that have arisen in the therapeutic application of the Becquerel rays. In 1900 Walkhoff observed certain peculiar changes in the skin caused by radio-active substances, which are analogous to the dermatitis produced by the Roentgen rays. Becquerel noticed in his own case, that carrying a highly active radium preparation in his vest-pocket produced a deep and persistent inflammation in the skin beneath, which spread and terminated in a deep-seated abscess. The repetition of this observation by others has led to the term "radiogenic inflammation." The therapeutic application of this radio-active substance rivals that of the Roentgen rays in tuberculous and carcinomatous disease of the skin. No explanation of the effect of the former on normal and pathological tissues has been forthcoming, except that it consists of a primary cellular degeneration with secondary reactive inflammation. This peculiar necrobiotic change in the cells following an exposure to the rays sometimes of not more than five minutes, not immediately, but only after a latent period of several days, has awakened investigation. Gresel observed that paper in which radium has been kept becomes brown and brittle, and ascribed these changes to molecular attraction which he assumes by analogy to take place also in living tissues. These and other researches stimulated the author to study the physiologico-chemical effects of radium rays, and for this purpose he availed himself of that veritable store-house of chemical and physiological facts, the hen's egg. Exposure of the latter to the influence of radium rays for 44 to 144 hours produced, in the sense of a dry distillation, a decomposition of the albuminoids. No marked changes are produced in native albumin. The organic pigment, lutein, a lipochrom contained in the yolk is decolorized. There is an important electric action in the lecithin, which is decomposed. This substance, allied to the fats, contains nitrogen in the group cholin, which is bound to the phosphoric acid constituent, and by virtue of its nitrogenous content is revealed its derivation from albumin. Its decomposition takes place with the addition of water and results in the formation of stearic acid, glycero-phosphoric acid and cholin, which last splits off trimethylamin. According to Verworn, lecithin is a splitting-product of albumin, like the nucleins, with which it is associated. It is a necessary constituent of all living cells, being united in some unknown way with the albumin of the protoplasm. According to Hoppe-Seyler, the presence of lecithin in large quantity in developing cells or in those capable of development, associated with cholesterin in the yolk of the egg, spermatozoa, colorless blood-corpuscles, rapidly-growing pathological growths and in many seeds and rapidly-growing parts of plants, indicates that lecithin bears a certain relationship to the metabolic events of cellular development. The influence of radium in decomposing lecithin would seem to explain the peculiar effects wrought by this substance in the cutaneous and adjacent tissues. The continual exfoliation and regeneration of the epidermis requires the presence of a considerable quantity of lecithin in accordance with the rule that this substance is found in largest amounts in those tissues undergoing active development. The necrotic and inflammatory changes in the skin produced by radium can therefore be explained upon the basis of the loss of lecithin through decomposition. The action of the Roentgen rays in retarding or arresting the growth of carcinoma and lupus of the skin would therefore be accounted for by this fact namely, that the lecithin which is abundant in all neoplasms and evidently plays an important rôle in their growth and development, is destroyed by prolonged exposure to the influence of these radiations.

The Effect of Various Essences on the Cerebral Circulation.—In experimenting with the essence of absinthe and with the essential oils of anis, citron, melissa and canella, A. D'Ormea (Arch. Ital. de Biol., Nov. 21, 1903) found that when injected into the circulation in a dose not capable of producing convulsions, these substances have the following effects on the circulation of the brain: A more or less rapid and durable depression of the circulation in the circle of Willis, associated with a rise of the subarachnoid pressure. Anis and citron produce the mildest effects while melissa and canella act more powerfully and sometimes even in small doses produce convulsive seizures. Camphor produces a still stronger effect, which may include a general convulsion frequently resembling in form and intensity, that caused by essence of absinthe.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 2, 1904.

DIRECT HEART MASSAGE.

The recent announcement by Dr. W. W. Keen, of Philadelphia, that direct massage of the heart, after an opening has been made through the diaphragm, might prove life saving in certain serious cases of apparently fatal collapse in abdominal operations when the patient is under an anesthetic will not prove so surprising to the medical profession generally, as it apparently was to the public, from the space given it by the newspapers.

For some time it has been understood that direct heart massage might accomplish a very definite life saving purpose in these extremely annoying and unfortunate cases. In recent years it has been the custom of Prof. Richet, of the University of Paris, to demonstrate in his course on physiology the possibility of apparently restoring dogs to life by the method of exposing their hearts and intermittently squeezing them with the hand. Animals that had been drowned and were to all intents and purposes dead are thus brought back to life. If the heart massage were not instituted in these cases the animals would never breathe again. As it is, though the heart-beat and respiration have ceased and the animals have been for over three minutes under water, after a time the heart begins to beat again, under the irritation of the massage and with the aid of artificial respiration; complete restoration to life follows.

Even before Professor Richet's experiments and demonstrations there had been more than a suspicion that irritation of the heart muscle itself might lead to revival after apparent death. Certain of the measures used in the production of artificial respiration and recommended for application after persons have been rescued from the water in an unconscious condition, seem to take advantage of this principle. It was recommended, for instance, that firm pressure should be made over the thorax anteriorly with intervals of relaxation. In asphyxiated newborn children intermittent pressure upon the thorax has always been considered an important part of revival methods. Even the ordinary artificial respiration, as conducted in the laboratory under forced air pressure, on an intubated animal, has something of this same principle in it. The alternate expansion and contraction of the thorax, under forced air pressure, acts as an irritant to the heart by alternately pressing the lungs against it, and then allowing them to contract away from it.

From this, of course, to actual incision of the diaphragm and the taking of the heart of the human being in the hand for purposes of massage is a long step. It is, however, one that has been gradually led up to, as have most of the practical discoveries in medicine and surgery, and there seems no doubt of its entire justification under the serious circumstances in which it is recommended. It is not attempted until the patient has been for at least five minutes without active respiration. To all intents and purposes such a patient is dead and the added risk of entry to the thorax through the diaphragm is therefore completely justified. That such a procedure may be successful, Dr. Keen's own reported case is the best proof. Notwithstanding that more than five minutes had passed since the heart had ceased to beat, under massage it resumed its pulsation, and though the patient died about half an hour later, there is no doubt that a new chance for complete recovery had been given, and only for the patient's cachectic condition, the case was one of total laryngectomy for cancer, the new life opportunity thus afforded would not have been in vain.

How long after apparent death such a procedure may be employed with some hope of success it is yet difficult to say. Great encourage-

ment, even after many minutes have passed, is afforded by certain experiments, which were undertaken in order to obtain additional physiological data for the procedure. The hearts of animals after removal from the bodies had been frozen for over two days and yet were made to renew their pulsations or at least make a certain number of spontaneous contractions and relaxations as the result of well-directed massage. It would seem then that this procedure might well find a place in attempts to restore to consciousness those who have been under water for some time, whenever all other methods of resuscitation have failed and the patient is about to be given up for dead.

It has never been absolutely decided how long after the patient has been under water, death is inevitable. In animals five minutes usually sealed their fate until this new procedure added to the means of resuscitation. In human beings occasionally resuscitation has been accomplished by previously accepted methods, even after twenty minutes, though the cases are rare and those of longer immersion with subsequent resuscitation are not well authenticated.

It is perfectly possible that this new method, which has been employed altogether over twenty-five times now and in two of them with such complete success as to restore apparently dead patients to life, may prove a very important addition to modern surgical therapeutics. At best, however, it will have a very limited field of application. It is more the sensation produced by the unusualness of the procedure of actually handling the heart in order to irritate it into renewed contraction than its possible frequent usefulness that brings it so prominently before the public now. It is but the further step in the surgery of the heart that has been developing in recent years from the first successful case of suture of the organ after injury, until now when even serious incised wounds, of the left ventricle particularly, are not likely to prove fatal if the surgeon recognizes the condition and has the courage to treat it by such direct surgical methods as he would apply to any other incised muscle.

"A FLORIDA ENCHANTMENT."

Florida has long been celebrated for her oranges, but if the inhabitants of her rural districts, with their antiquated and bucolic habits, still continue to measure their faith by the traditional Biblical standard, their grains of mustard seed must have increased to even a greater extent than the rest of their tropical fruits. At all events, Mrs. Helen Wilman-Post has been reaping a golden harvest, and might, it seems, have still been making daily bank deposits of large sums had she not, like Bonaparte, met with a Waterloo, and also, like Bonaparte, encountered it in an unexpected manner and from most ignoble hands.

According to the evidence produced at Jacksonville, Mrs. Post was a "healer," not only of large experience, but of even greater promise, for the list of the miracles which she guaranteed to accomplish by her mental treatment comprised the following acts: "To get a man out of jail; make a new set of teeth grow; make a leg grow on a stump from which the lower leg had been amputated; make the hair grow on a bald head; restore the affections of persons who had become estranged, ensure success in speculation, transfer the affections of persons."

Now the wants of the human kind are very much the same the world over, whether they live in an ordinary every day manner, in huts bordering on the sluggish Wilhlacooche river, or if they reside in a Sunday-like, holiday way, in brown stone houses that are washed by the receding tide of the Atlantic, in the "Back Bay" precincts of classic Boston. Moreover, there are not many ordinary beings who would not be assisted by the materialization of some of these promised benefits. While there are very few who unless possessed of a carping and discontented spirit would not have been satisfied with the list as originally given. In order, however, to insure perfect satisfaction to those desirous of obtaining her professional services, Mrs. Post issued a second circular of approved medical "stunts" which was to the first what the dress white tie is to the evening coat of civilization. These were: "To insure the birth of children; to check the undue size of families, and to regulate the sex of future offspring." This having been accomplished, the Florida Enchantress rested from her labors. Her web had been woven. It was of steel wire, copper fastened and clinched, and she did not believe that a fly from any ointment could escape its meshes.

The weeks rolled by, and the money rolled in, bills of large amount, notes of small denomination, but always money. Teeth were reported to be growing in gums long smoothed by age. Convicts were released as their terms expired; delicate rootlets of hair were believed to be germinating in polished scalps, and all went merry as a marriage bell. The offices grew and extended, the

number of clerks who were sending glad tidings of great joy to all manner of men and women, increased, and printed answers to the questions of eager inquirers were now beginning to flood the mails. Then ensued a plethoric golden age, in which unbounded success relaxed the caution that had hitherto kept the machine in motion. It appeared at the trial that Mrs. Post no longer read her mail, but after extracting the enclosed money entrusted the answering of the letters to clerks, who either forwarded printed circulars, couched in glittering generalities or consigned them unacknowledged to the yawning void of waste-paper baskets. The complaints began to increase and multiply, and with the charge of "using the United States Mail to defraud various persons" came the bursting of the South Sea bubble in the sandy dunes of Florida.

There is a moral in all true tales, and the saddest part of the mishap of this modern "Belle Helene" lies in the fact, that she has never recognized the little acorn of discontent from which the great oak of ruin, that gradually overshadowed her prosperity, grew. Nor did she know the wood-woman, who not only would not spare the tree but whose feeble fingers first laid the glittering axe at the roots of her affluent success. Somewhere down in Citrus County, in the interior of the State, there lived a woman, one Mrs. Casey, who not only had been wooed, but according to her "marriage lines" had also been won by the most selectman of the selectmen of her native town. From then on her life seemed marked with success. Endowed with great executive ability, and possessed of a lively interest in the affairs of others, she for years sat at the right hand of her selectman, from whence, according to her neighbors, she came to judge both the quick and the dead. The one weak spot in her heart was for her pet dog, towards which her fancy, after the manner of her sex gently, turned to thoughts of love. The New England spinster of uncertain age may devote herself to her tabby, of an equal uncertain sex, while the up-to-date American girl, since the Spanish war, will waste her sweetness on the unresponsive marmoset and the changeable chameleon, but with the women of the South a yellow dog it has always been, and a yellow dog it will always be 'till suns shall rise and set no more.

Unfortunately Mrs. Casey's particular specimen was either a truant dog that thought his home a cage, or he was possessed of a desire to wander from his own fireside that could not be eradicated. At all events he departed from home and mother on a certain sultry day, and she refusing to rest under the consoling thought that it was better to have loved and lost, started after him in an equally sultry pursuit. Both the woman and the dog became engrossed in the match and were utterly unconscious of the fact that it was taking place between the yellow pine rails of a local freight line until an engine coming round a curve met the lady full and fair in the midst of herself and her career. What appeared in the local papers was merely an announcement of the escape of the dog, coupled with the bald and bare statement, that Mrs. Casey had been "hurt some." The "some" referred to being a compound comminuted fracture of the arm and a loss of the left leg just above the knee. The locomotive was an alien, an imported stranger, but it seems to have done its work thoroughly, as the limb, which was buried with the full rites of the church, proved conclusively that it had not bitten off more than it was perfectly able to chew.

Years passed and the wounds had healed, but Mrs. Casey never smiled again or ceased to repine that in all the things she was not "as other women are." It was not that the taunts of ribald boys, with their scoffing allusions to "peg leg" and "dot and carry one" broke her proud bearing, nor yet her inability to join in the merry dance, but rather a personal sense of a loss of equilibrium, and a constant desire to reestablish, on the old lines, the accustomed meta-centric balance of gravity. She might, like the centurion of old, say to one "come," and to another "go," but as long as she was personally unable to supervise the execution of her commands, the exercise of her almost despotic power found but little favor in her eyes. It was at this critical period that the illusive and flamboyant circular of Mrs. Post fell into the outstretched hands of Mrs. Casey, and the beginning of the end had come. But oh, what rapture; as to love she had it, as to teeth she was indifferent, bald she was not, but how doubly blessed was the "healer" who could make even one leg grow where one had grown before. The farm was mortgaged and the proceeds sent to Jacksonville. Day followed day, and the faith in the efficacy of the cure waxed and waned with the tides and the moon. The instructions were implicitly followed out, but the leg that she had looked for never came.

There is a trite injunction fed to each baby with his mother's milk, in the cattle raising districts of the South, "Never give a bullock sul-

phur or you will repent it," and to this may be added, never feed a "cracker" woman "taffy," or fail to keep a contract with her paid for in advance. For from selectman to selectman the story of Mrs. Casey's wrongs traversed the hummocks and bayous of her native State, and from postmaster to postmaster spread the news of the sinful pulling of her leg. Then came the power and might of an outraged government, with its illegally-used mails, and the career of Mrs. Helen Wilman-Post was at an end.

The interest from a scientific standpoint lies in the fact, that this case directly confutes the allegations of these "Mental Healers" who claim that their failures, in all cases, are due to a want of faith on the part of those treated. For here *was* faith, and faith to spare. Faith that could not only move mountains, but faith that attempted to move Mrs. Casey, who was equally as massive, and perhaps a little more inert.

THE LONG BACILLUS OF THE STOMACH CONTENTS.

The long bacillus, which is so constantly found in the stomach contents in cases of carcinoma, has attracted the attention of many investigators. It was first discovered by De Bary, Jr., who named the organism *Bacillus geniculatus,* but failed to attach any special significance to its presence. Minkowski pointed out its predominance in bacillus fermentation associated with extensive production of lactic and butyric acids. Boas then drew attention to the importance of the long bacilli in the differential diagnosis of cancer of the stomach, and showed that their demonstration may be regarded as collateral evidence of the presence of lactic acid. The first description in greater detail came from Oppler. Since then it has been spoken of as the Boas-Oppler bacillus. The clinical significance of this organism, as first formulated by Boas, has now been definitely established. Instances, it is true, have been recorded in which the bacillus has been encountered in non-cancerous affections of the stomach, but such occurrences are after all rare and do not detract materially from their diagnostic importance. This is practically the same as that attaching to the presence of lactic acid.

The question why these organisms should occur so plentifully in carcinomatous stomachs has long been a subject of speculation. Possibilities which suggested themselves were (*a*) the anacidity of the gastric juice with simultaneous stagnation of the stomach contents; (*b*) the irregular contours and depressions of the surface of the tumors, and (*c*) the admixture of blood to the stomach contents. Each one of these factors no doubt is of moment.

A perfectly satisfactory explanation of the reasons why in advanced cases of the disease the long bacilli control the situation to the exclusion of almost all other forms has, however, not been furnished until recently. Sandberg's researches, which appeared a short while ago, have thrown new light on this problem. Using one per cent. glucose agar this investigator succeeded in isolating two types of the organism in question from carcinomatous stomach contents. One of these was represented by short bacilli, the other by the typical long bacilli. Their identity was proven by the demonstration that one type could artificially be caused to pass over into the second type. The short type the author regards as the primary form. Associated with these two types carcinomatous stomach contents may contain one or more other forms of lactic acid producing bacilli, and it is interesting to note that on artificial media these forms develop much more rapidly and readily than the long bacilli, although in the stomach contents they are far less numerous. Their acid production, corresponding to the greater activity of their growth on artificial media is also much greater. These peculiar results find their explanation in the fact that while the acid production of the common lactic acid bacillus is at first much more active than in the case of the long bacillus its growth is arrested already by a comparatively low percentage of lactic acid. The growth of the long bacillus, on the other hand, is thus rendered more vigorous. This was shown in a series of ingeniously arranged experiments. Sandberg prepared an artificial culture medium, which represented the patient's own gastric juice, sterilized by means of chloroform, to which glucose was further added. Tubes of this medium were then inoculated with the two types of the long bacillus and the common lactic acid producers which had previously been isolated. In one experiment, in which the medium contained 1.9-1,000 of lactic acid, it was found that the two types of the long bacillus had grown very actively, while in the remaining tubes no growth had taken place. In the presence of 3-1,000 of lactic acid the long bacillus did not grow so readily as in the first experiment, while the other tubes again remained sterile. In a third experiment in which the stomach contents contained 1.4-1,000 no growth even of the long bacillus occurred.

The appearance of the long bacillus in almost pure culture, in cases of carcinoma, thus finds its explanation in the resistance which the organism offers to lactic acid in concentrations, which will arrest the growth of the common lactic acid producers. These latter probably furnish the primary grade of acidity, which is especially favorable to the growth of the long bacilli.

Opposed to the validity of the above explanation is apparently the fact that isolated cases of carcinoma have been observed in which the long bacillus was present even though lactic acid could not be demonstrated at the time. In such cases it is possible that the bacteria may have developed in nooks and crevices of the carcinomatous portion of the stomach, where conditions favorable to their growth may have been present, even though the gastric contents as a whole may not have proved a suitable medium. This factor, as we have pointed out, has already been suggested as of moment in the explanation of the predominence of the long bacillus in carcinomatous stomachs. That such a condition should favor the occurrence of fermentative processes even in the absence of stagnation of the stomach contents is scarcely to be doubted, and probably also accounts for the frequency with which certain protozoa (*Trichomonas intestinalis, Megastoma entericum*, etc.) are simultaneously encountered.

MARAGLIANO'S VACCINATION.

The name of Jenner has become synonymous with savior. In those days when medical textbooks described smallpox as an inherent humor which must out in every man, and where it was the prevailing opinion that as no one could escape it, it was better to have it and be done with it, in those days we can see that it must have been hard indeed to have established the use of such an unprecedented custom as vaccination.

Until the last few years of the nineteenth century, the popular view of tuberculosis has been almost as fatalistic. But from Koch to Maragliano there has been an uninterrupted procession of investigators who have marched forward with careful haste; and have carried the flag of conquest almost into the citadel of death.

If tuberculosis can be as completely controlled as smallpox has been, the greatest curse of disease will be lifted from the land. In the original contribution of this week, prepared by Prof. Edoardo Maragliano, of Genoa, Italy, and read at the Henry Phipps Institute on last Monday night, we see that it is possible to produce a specific serumtherapy for tuberculosis, and that there is good reason to hope for vaccination in man as a preventive of the spread of the disease.

It all depends upon the enterprise with which Prof. Maragliano's methods are tested upon a large scale, whether it is a half-century or but a few short years before the value of his and his colleagues' work is felt all over the civilized world.

The energy and wisdom shown in the adoption of antitoxin of diphtheria has illustrated what can be done, when laboratories, health departments and great business institutions work together on an approved scientific basis. The bacilli of diphtheria work with such lightning rapidity that the rescue from the disease is almost spectacular; and the public has needed but little coercion to adopt the treatment. Also the onslaught of the disease is so decisive that there is no time to waver and doubt. But the slow, insidious progress of tuberculosis and the tendency to delay diagnosis until the serumtherapy will prove of no avail will combine to make the public doubt the efficacy as well as the necessity of such treatment as well as of vaccination.

Dr. Maragliano begs for a wide test, which implies years of work, but such work is just the kind that the generous founder of the Henry Phipps Institute had in mind. Means, equipment, workers, leisure, and a great desire to bring things to pass, are all necessary if one would establish the machinery that will make a scientific theory lift a part of the world's burden. These the Institute possesses as no other in the world. And it would seem as though it were best fitted to carry out the charge.

We feel that if the workers of the Henry Phipps Institute satisfy themselves that these methods are practical for application on a large scale, it will not be too much to expect that they will indicate the lines by which the serum shall be manufactured, and distributed, and also undertake the propaganda of the treatment with the systematic cooperation of health departments.

Bacteriology of Conjunctivitis of Measles.—In the majority of cases of measles examined by E. Schottelius (Münch. med. Woch., March 1, 1904) the *Staphylococcus aureus* was found in the conjunctival secretion, less frequently the other varieties of staphylococci and in especially severe cases, streptococci. These did not correspond exactly to the ordinary pyogenic streptococci, as they did not grow below 30° C. and behaved somewhat differently toward aniline dyes. When examined in the dried state, they often appeared as diplococci, but the hanging drop showed distinct chain formation. The findings point to a possible pyogenic infection as cause of measles.

ECHOES AND NEWS.

NEW YORK.

Hospital Appointments.—The following men from the College of Physicians and Surgeons have secured hospital positions: Bellevue—C. K. Stillman, first place; W. C. Cramp, J. T. Pilcher, J. F. Bowman. Mt. Sinai—A. E. Cohn, Max Taschman, J. J. Meyer, Louis Jacobs, S. Wiener. German Hospital of Brooklyn—B. S. Harris. Bridgeport (Conn.) Hospital—C. H. Sprague.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission announces general examinations to be held April 19, 1904, including physicians in State hospitals and institutions of both regular and homeopathic schools. Applications for these examinations must be made on or before April 14. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

Physicians and Surgeons Announcement.—The annual announcement of the College of Physicians and Surgeons has just been issued. It is a pamphlet of sixty-four pages. Two new names appear among the officers of instruction: Dr. Harry McMahon Painter, professor of clinical obstetrics, and Dr. Gorham Bacon, clinical professor of otology. The following new appointments have been made: William K. Simpson, clinical professor of laryngology; Philip H. Hiss, adjunct professor of bacteriology; Eugene Hodenpyl, adjunct professor of pathological anatomy; Francis Carter Wood, adjunct professor of clinical pathology, and Frederick R. Bailey, adjunct professor of normal histology. New courses will be offered in the departments of materia medica, pharmacology and therapeutics, of pediatrics and of physiological chemistry. More extensive work than ever before will be given in pharmacology and therapeutics under the direction of Prof. Christian A. Herter, and considerable attention has already been directed toward the development of a thorough pharmaceutical laboratory, under the care of Drs. Jelliffe and Bastedo. The work in general chemistry, heretofore given under the direction of the Columbia University department of chemistry, in the future will be in the hands of Professor Gies, head of the department of physiological chemistry at the Medical School. Three courses will be offered in general organic, inorganic, and physical chemistry in addition to the regular work in physiological, toxicological, and botanical chemistry.

Hospitals at Their Fullest.—The current issue of *Charities* says that "a census of all the municipal hospitals and the general private hospitals of New York shows that the unusual number of patients has been continued very steadily through the winter, and that the total number of patients in twenty hospitals on March 19 was greater than on January 23. On the former date the total was 5,202, and on the latter 5,390. As the capacity of the hospitals is given as 5,446, there are now, on paper, only fifty-six vacant beds in all the general hospitals of New York. As a matter of fact, the distribution of vacancies makes the condition look much better than at first appears. In the city and metropolitan hospitals, conducted by the Department of Public Charities, there are 200 more patients than the capacity. In Bellevue and allied hospitals, patients and capacity are about even. In the private hospitals there are at least a few vacancies in each, and in some a fair number. The condition in the city and metropolitan hospitals has been held to be the naturally expected result of a very severe winter. These two hospitals are the places of last resort for the sick poor, and the sick poor are more exposed to and suffer more from the rigors of such a winter as the one just passed than any other class. Hence the crowding on the island hospitals. Another factor out of the usual is the fact that for three weeks preceding the date of removal to its new buildings, Mt. Sinai Hospital refused to accept any patients, so that on March 19, when this census was taken, there were only 28 patients left in the old building and none in the new. Undoubtedly this raised the numbers in other hospitals. The average number of patients at Mt. Sinai from January to March was 205 daily. Changes in the children's ward at the Presbyterian Hospital also made a difference, as a part of this ward was temporarily closed in January. It appears, therefore, that conditions now are really worse than in January when there was the most talk and newspaper comment on the congested condition. But the hospitals have met the tax on their resources and, except in the municipal hospitals on the East River islands, are in good shape to deal with the epidemic of grip and pneumonia. It was stated at a number of them that with the real opening up of spring and warm weather the number of patients may be expected very materially to decrease."

New York Academy of Medicine.—The next meeting of the Pediatric Section will be before the whole Academy on April 7, 1904, at 8:15 P.M. Following is the program: 1. Modes of Infection in Tuberculosis, by Philip S. Sabine, M.D.; 2. Infantile Tuberculosis, its port of entry, topography and clinical manifestations, by Rowland Godfrey Freeman, M.D.; 3. The Influence of Bovine Tuberculosis on Human Health, by Mazyk P. Ravenel, M.D., of Philadelphia; 4. The Prevention of Tuberculosis in Children, by Hermann M. Biggs, M.D.; 5. Discussion of the Papers, by Dr. Thomas Darlington, Commissioner of Health; Drs. W. P. Northrup, Emmett L. Holt, C. N. Dowd, S. M. Hamill, of Philadelphia, and others.

Prof. Lefferts' Farewell Lecture.—On Monday, March 28, Professor George M. Lefferts gave his farewell address to the clinical assistants and Class of 1904 at the Vanderbilt Clinic. The pit was very tastefully decorated and three larges vases were filled with roses and placed on the speaker's table. Upon the Professor's entry into the room the audience arose in a body and applauded for nearly five minutes. Following this, George Lathrop, President of the Senior Class at the College of Physicians and Surgeons, presented a costly loving cup in behalf of the students and spoke very tactfully and feelingly of the regard in which Dr. Lefferts has so long been held by generations of medical students. Dr. W. K. Simpson, who will succeed Dr. Lefferts as professor of laryngology, then arose and in a fitting speech presented a loving cup in behalf of the clinical assistants. In accepting the gifts Prof. Lefferts said that doubtless popularity has its advantages, but it also has its disadvantages, for now he too would be obliged to make a speech, but in anticipation of their demands upon him he had come forearmed (withdrawing a manuscript from his pocket). He had learned to know the method, manner and meaning of medical students' applause through his long years of teaching and felt that he could interpret rightly their very kind feelings on this present solemn occasion. For thirty years he has engaged himself in active teaching of laryngology, and when he began nobody elected his course because it seemed of so little practical value to the general practitioner. His

was the first clinic of the kind in New York and the third in the whole United States. In May, 1876, he was made a full Professor with the power to organize and control the clinical work of the department. So well has this been done that the Class of 1900 offered to the Faculty the opinion that his clinic was the best systematized and best adapted for medical teaching of any in the college. By a vote of the Faculty and Trustees of Columbia he has been made Professor Emeritus and it is his hope that his administration will be accepted by all men as able, dignified and honorable. His entire collection of teaching apparatus has been presented to the Trustees "for the benefit and free use of coming generations of medical students." All this he said in no spirit of vain self-glorification, but the love for his clinic has grown with the years and of this he speaks not of himself. In addressing Dr. Simpson he said that he believed him to be earnest and devoted to the work which he has carried on at Vanderbilt Clinic for seventeen years. It is not so much the matter or subject that one has to present as his manner of presenting it, and in offering this advice he wished his successor Godspeed. All the members of Prof. Lefferts' family were present, including the nurses who had served him so long, and the exercises made a deep impression upon them as well as upon the general audience.

PHILADELPHIA.

New Society Against Tuberculosis.—The delegates called to meet in Philadelphia to consider the founding of a national society against tuberculosis were entertained at dinner on the evening of March 28 by Dr. L. F. Flick. Abstracts of the address that was to have been delivered by Professor Maragliano, who was detained by illness, were distributed. The meeting held afterward was presided over by Dr. William Osler. After some discussion it was decided to found a National Society for the Prevention of Tuberculosis. An executive committee consisting of Drs. Trudeau, Biggs, Flick, Welch and Sternberg, with the chairman and secretary of the meeting as members *ex officio*, was appointed. This committee is to have full charge of arrangements for perfecting the new organization, including election of officers, etc. It was the sense of the meeting that the new society have no affiliation with either of the so-called International Congresses on Tuberculosis now under way in this country. The name of this new society is the United States Society for the Study of Tuberculosis. The President is Dr. William Osler; Secretary, Dr. Henry B. Jacobs. The committee of five was appointed to plan a permanent organization to be effected at the meeting of the American Medical Association at Atlantic City in June.

Philadelphia Hospital Examination.—At a conference between the Mayor and the deans of the various medical colleges it has been decided to hold the examination of candidates for internes at the Philadelphia Hospital on May 10. The Mayor will appoint the members of the examining board who, it is stated, will have no affiliation with any of the medical colleges. There are 19 vacancies to be filled, and it is said that if 19 women get the highest marks they will be appointed.

Attempts to Form Nose Unsuccessful.—Two attempts have been made by Dr. Charles H. Frazier, at the University hospital, to form a nose for a young man who lacks that organ. Each time the patient has spoiled the results of the operation and it is said that further attempts may not be feasible. The fourth finger of the patient's hand was fastened to the desired place but the pain of keeping the arm in the necessary cramped position was too great for the patient who each time tore the finger loose.

To Enforce Vaccination.—A bill giving the Department of Health power to enforce vaccination is to be introduced into the next legislature. The only compulsory vaccination law now in force in Pennsylvania is that relating to school children, although vaccination may be made partially compulsory in cities of the second and third class.

American Society of Tropical Medicine.—At a meeting of this society held March 21, Dr. W. M. L. Coplin exhibited specimens illustrating diseases of the tropics, including dysentery, abscess of liver, leprosy and uncinariasis. Dr. McConnell exhibited for Dr. Joseph McFarland some specimens of the Leishman-Donovan blood parasite, through the courtesy of Sir Patrick Manson, an honorary member of the society. Dr. J. M. Swan showed for Dr. Allen J. Smith gross specimens of the *Hymenolipsis nana*. Election of officers for 1904 resulted as follows: President, Dr. Thomas H. Fenton; Vice-Presidents, Dr. J. J. Kinyoun, Dr. James M. Anders, Dr. Alfred Hand, Jr.; Secretary, Dr. Joseph McFarland; Assistant Secretary, Dr. John M. Swan. The Councilors for the year are Drs. Roland G. Curtin, Judson Daland, John V. Shoemaker, Allen J. Smith and W. M. L. Coplin.

Filters to Lower Typhoid Rate.—Chief Hill, of the Filtration Bureau, from a statistical investigation of the cases in the city at present says that when the filtration is completed the typhoid rate will be lowered at least 80 per cent. This is based on the comparison of cases for the past eleven weeks in the Twenty-first and Twenty-second wards, which have filtered water, with those in the remainder of the city. In the former the weekly average for each 100,000 of population was 3.7 cases; in the latter it varied in different localities from 10.4 to 13.8 cases. The present epidemic is not abating.

Cerebral Form of Grip.—Physicians report as epidemic a form of the grip that in its first stages is difficult to differentiate from meningitis. There were 8 deaths from the disease last week. It is estimated that 8,000 persons are now under treatment for the disease in its various forms.

Anniversary Dinner.—The anniversary dinner of the Henry Phipps Institute was given by the Staff at the University Club on Monday evening, March 28. The delegates to the convention, which was called to consider the question of forming a National Organization for the Study of Tuberculosis, were all invited as guests of the occasion. Sixty-two persons were present, among whom were many of the most eminent physicians of the United States. The feature of the evening was the presentation of a silver pitcher to Dr. Lawrence F. Flick, the Director of the Henry Phipps Institute, by the members of the Staff, as a token of their esteem. Mr. Henry Phipps, the founder of the Institute, was present, and made the presentation in the name of the Staff. Among those who spoke after dinner were Dr. Abraham Jacobi, of New York; Dr. William H. Welch, of Johns Hopkins University; Dr. Vincent Y. Bowditch, of Boston; Dr. John M. Prior; Dr. Charles L. Minor, of Asheville, N. C.; Dr. George M. Sternberg, former Surgeon-General of the Army; Dr. John B. Huber, of New York; Dr. Ward, of Albany, N. Y.; Dr. Henry B. Holton, of Brattleboro, Vt.; Dr. John Musser and Dr. James Tyson, of University of Pennsylvania, and Dr. J. C. Wilson, of Jefferson Medical

College. Dr. L. F. Flick acted as toastmaster and chairman, and Dr. M. P. Ravenel spoke for the Staff of the Henry Phipps Institute.

CHICAGO.

Chicago Medical Society Endorses Emergency Hospital.—This Society, at its March 16 meeting, endorsed the project of the Iroquois Memorial Association to erect an emergency hospital in the business section of the city, and the following resolutions were unanimously adopted: *Resolved*, That this Society approves and unqualifiedly endorses the action of the Board of Trustees of the Iroquois Memorial Emergency Hospital in their generous effort to give to the people of Chicago a modern, fully equipped and endowed hospital, capable of rendering prompt assistance to those cases of unexpected injury and sickness, which are of daily occurrence, and be it further resolved, that we, as a Society, tender to the hospital our counsel, advice, and professional services whenever required.

Necessity for Iroquois Memorial Hospital.—According to Commissioner of Health Reynolds, necessity for such a hospital may be inferred from the following statement of cases handled by the police of the district north of Harrison street during 1903: Number of casualties, 734; number found unconscious, 56. These cases were all removed to hospitals by the police, and the total does not include fully 10 per cent. more injured persons removed to their homes, many of whom were severe cases, who should have been taken to a hospital but for the distance. Nine of the 790 cases died en route to the County Hospital, an average distance of more than two miles from where they were injured, over rough, ill-paved streets. Those found unconscious were chiefly persons suffering from fracture of the skull or from poison; some of these died who might have recovered with prompt hospital care. Another class found unconscious, which especially needs the medical skill of experts, embraces cases of coma, the result of disease, and not from alcohol, which latter it closely resembles in its symptoms. A downtown emergency hospital, thoroughly equipped, is a necessity.

Medical and Dental Professions Unite on Questions of Legislation.—The Chicago Medical Society and the organized dental profession agree that all questions of legislation and larger public policy relating to medical and dental affairs shall be referred to a committee, to be known as the Committee on Public Relations. This Committee is to consist of ten members, five from each profession. It shall have a Chairman and a Secretary. Any question of public policy or public relation affecting either the medical or dental profession, or of legislation affecting directly or indirectly either of them, can be referred to this Committee. It will be the duty of the Committee to carefully consider these questions. It will have the power to recommend either specific action or general attitude to the societies from which the members come as delegates. There shall be an annual meeting of the Committee at which organization shall be effected and continued. Other than this the meetings shall be special, and can be called by the President or by any two members. The officers shall be elected for one year. The method of election of the delegates and the length of their service shall be regulated by the societies which they represent.

Sarcoma of the Hip Joint.—Dr. Wagner demonstrated before the North Branch of the Chicago Medical Society a patient upon whom he had performed a hip-joint amputation for sarcoma five years ago, with absolutely no signs of recurrence. The patient was fifty-five years of age; the picture of health, and weighs more now than at any period of his life. The stump, a solid, heavy upholstering of good muscular tissue, shows the scar of the incision very favorably situated, namely, so high anteriorly that when the patient is seated on a chair it is far removed from any pressure. This method of operation shows the great advantage of the use of long vulsellum forceps inserted in both flaps to the number of three or four as forceful hemostats, as well as their superiority to retractors. Inasmuch as the latter may slip, tear, and through their insertion and reinsertion mutilate the tissues and increase hemorrhage, hemorrhage is avoided or fully controlled by the forceps mentioned above. They facilitate greatly the manipulation of the flaps; after their insertion, large compresses are placed between the flaps, and then by means of dovetailing the forceps steady compression for a short time is exerted. This insures absolute hemostasis. The flaps are then slowly and gradually separated, the blood vessels caught with small hemostats just as they appear on the small exposed area, etc., until all the blood vessels are within the grasp of the hemostats which renders the operation almost bloodless. This procedure is preceded by ligating the femoral artery. For closing the wound a silk suture, guarded with rubber tubing, was employed. The author frequently uses this suture material for uniting the flabby abdominal walls, and it was used in this case with great satisfaction. Microphotographs made by Dr. Herzog from the specimen which had been dissected out of the tumor several weeks previous to the operation confirmed the diagnosis of sarcoma, and in which Prof. Nicholas Senn, Dr. Daniel R. Brower, and Dr. Wagner concurred. Dr. Wagner reported three additional cases.

Penal Hypospadia.—The patient, fourteen years of age, was operated on two months ago. The same method as Carl Beck described in the *New York Medical Journal* for 1898 for balanitic hypospadias was resorted to, namely, two lateral incisions from each side of the median line along the sulcus corona glandis, fusing in an incision following the urethra towards the scrotum, 2½ inches in distance, were made. The urethra was dissected out, and then pulled through the opening which was established by running a double edged knife through the glans penis in the direction which the normal urethra takes, and the distal part of the urethra, after being pulled out through this opening, was sutured with catgut to the external opening of this new canal. The wound edges of the flaps were then united, followed by primary union. After the lapse of fourteen days the new opening contracted, which necessitated splitting of the meatus and suturing. By means of the daily use of a sound the meatus has remained satisfactorily patent. It is interesting to note that during the healing period there was no inflammatory reaction from the urine passing over the wound. Furthermore, the patient did not experience any pain, not even during the first day. The use of a constricting rubber tube rendered the operation bloodless.

Extirpation of Metacarpal Bones.—Extirpation of the second, third, and fourth metacarpal bones (after loss of three fingers and crushing injury to the metacarpal bones with great defect of integument, volar as well as dorsal) with perfect functional result. This result was obtained by careful dissection and saving of the adductor pollicis and digitii mininti muscles

and the branches of the median and ulnar nerves which constitute the nerve supply for the muscles in question. At first, the fingers were in a paralytic condition, as one might expect, but by daily massage and the application of electricity by the author himself the patient (the hand has the appearance of a lobster-shears) has full use of the fingers which were affected and is now able to earn his own livelihood through caligraphy with this hand, and has also become an expert performer on the zither.

Radical Mastoid Operation.—Dr. Wm. L. Ballenger showed a young woman, aged sixteen years, who, about nine years ago, was vaccinated. The vaccination was followed by a discharge from the left ear, and as far as could be learned, it was the cause of the ear trouble. Four years ago she came under his observation, was treated by conservative methods for a year and a half, with only temporary relief. Three years ago he did a radical mastoid operation, finding cholesteatomatous masses in the middle ear and mastoid cavity, with suppuration, caries, and perforation in the middle fossa of the skull. There was marked meningeal irritation. The operation afforded relief, but subsequently there was necrosis in the mastoid portion of the wound, which necessitated a second operation. A few days following the second operation he resorted to Thiersch grafting in the mastoid portion, and a week or two later did a Thiersch graft in the middle ear cavity. At present the middle ear as well as the mastoid is completely lined with healthy skin. The case was interesting on account of the Fallopian canal being exposed, showing plainly the location of the facial nerve. The Eustachian tube was likewise visible through the mastoid wound. There only remained a little suppuration within the Eustachian tube. He expected to close the tube later, and having done it, the mastoid wound would be closed by a plastic operation, and the speaker hoped that with paraffin injections he would be able to avoid much deformity The patient is entirely well and has been since last October.

Left Bronchial Fistula.—Dr. Allen B. Kanavel reported a case of left bronchial fistula in a child of seven years, which has been present since birth. It is located at the most common site—within an inch of the sternoclavicular junction, and passes directly upwards towards the upper border of the hyoid bone. It cannot be followed farther, although when it fills up, as it does at times, any manipulation of the tract gives rise to a coughing attack. There is no cervical auricle, but the tract is marked by a firm band of tissue which is probably connective tissue. The other members of the family show no evidence of any congenital anomaly, with the exception of a brother who has hydrocephalus.

Coccygeal Sinus.—Dr. Kanavel demonstrated a second case of coccygeal sinus which was operated upon under the diagnosis of anal fistula. Upon operation, a large mass of hair and epithelial débris was found the size of a walnut, and the history was elicited that although the patient had suffered within the last year from an acute attack simulating an ischiorectal abscess, and this discharging sinus had been very marked since, still he had noticed a constant moisture and slight irritation for a number of years previously. The fistula was in the median line and about half an inch below the tip of the coccyx.

Some Notes on the Therapeutics of Tonsillitis.—At the March meeting of the Chicago Pediatric Society, Dr. J. Scott Brown, in a paper on this subject, after dismissing the subject of chronic tonsillitis with the remark that he considers a large percentage of the cases to be of the rheumatic type, and that he treats them locally and systemically with tincture ferri chloridi, the formalin and formalin iodine sprays, and Seiler's solution used as a douche for the nose and throat mentioned below, took up the treatment of acute tonsillitis, making special mention of the follicular variety. His routine treatment for such cases, basing dosage on the adult, is: Calomel, $^1/_4$ gr. every half hour, until six doses.

℞ Tr. aconite root..... gtt. $^1/_5$
Tr. bryonia..... gtt. $^1/_{10}$
Tr. belladonnæ..... gtt. $^1/_{10}$
Red iodide of mercury..... gr. $^1/_{100}$

In each tablet, given one per hour until eight per day are taken.

Quinine tablets, each gr. 1, are given every hour until eight are taken.

Alcohol and water, as a gargle is employed, t.i.d.

℞ Formalin (40 per cent. sol.)..... ♏ iii
Glycerini..... ʒ ii
M. et add
Aquæ, q.s. ad..... ʒ i
M. Sig.: Spray throat, t.i.d., between gargle.
And
℞ Formalin..... ♏ iii
Glycerini..... ʒ vi
M. et add
Tr. iodine..... ♏ xx
M. et add
Alcoholis..... ʒ iv
Aquæ, q.s. ad..... ʒ iv
M. Sig.: Use as a spray following immediately the last spray.

He says that part of the treatment is empirical, but that he finds his cases, even with temperature of 102° or 103° F., can generally return to their usual avocations in about forty-eight hours, and cited illustrative cases.

Undescended Testicle. The third case reported by Dr. Kanavel was one of undescended testicle on the left side. The testicle lies in the inguinal canal and has not changed its position for a number of years, and has given rise to no trouble until about a year ago, when, after a severe strain, a mass developed suddenly at the same site, followed almost immediately by a sickening pain characteristic of that usually experienced when a blow is received on the testicle. This was accompanied by vomiting. All symptoms would disappear as suddenly as they came on, when the mass was replaced in the abdomen. Repeated attacks of this nature helped to make the diagnosis of congenital hernia; the symptom was due to pressure from the distended cyst.

GENERAL.

Bubonic Plague in Peru.—United States Minister Dudley cabled the State Department from Lima on March 25 that bubonic plague had broken out in San Pedro, Callao, and Lima.

War on Mosquitoes in South America.—An active campaign against the spread of yellow fever and malaria, by an organized war against mosquitoes, has been started at Guayaquil, Ecuador, as the result of suggestions of Dr. Gruver, the resident officer of the United States Marine Hospital Service.

Medical Library and Historical Journal.—The first number of the new year of the *Medical Library and Historical Journal* has just arrived. It is an extremely attractive publication and merits the attention of the entire medical public. Dr. James J. Walsh has a most able article on the Popes and their relation to the his-

tory of anatomy, in which he shows that the Popes were not so greatly opposed to the study of anatomy, as some writers have affirmed. Dr. William Osler contributes an interesting account of the "Phthisiologia" of Richard Morton, and Dr. Isadore Dyer has an instructive study of the origin of the Louisiana leprosy. A short history of Winslow, and a brief paper on Medicine in Its Relation to Human Progress are other papers in this number.

Johns Hopkins University.—The medical department has announced the first course of lectures on the Herter Foundation. Prof. Paul Ehrlich, M.D., LL.D., director of the Royal Prussian Institute of Experimental Therapeutics, Frankfort-on-the-Main, will lecture in German, April 12, 13 and 14, on subjects related to immunity.

American Academy of Medicine.—The Twenty-ninth Annual Meeting of the American Academy of Medicine will be held at the Shelburne, Atlantic City, beginning on Saturday, June 4, at 11 A.M., and continuing through to Monday, June 6. The program includes: 1. The report of the Council on the recommendation of a paper read at the last meeting by Dr. H. Bert Ellis, of California, on "The Necessity for a National Bureau of Medicine and Foods." 2. The report of the committee to investigate the teaching of Hygiene in our public schools. In order that this report may be discussed intelligently, the committee will publish the laws relating to the teaching of hygiene now in force in the United States, in the Bulletin of the American Academy of Medicine, to be published in April, 1904. It is believed this is the most complete and accurate compilation of these laws published, and the only compilation issued in an easily accessible and low priced publication. (Any number of the Bulletin will be sent to any address upon receipt of 50 cents.) 3. The reports on the results of the examinations before the various State Boards of Medical Examiners of 1903. 4. A Symposium on the Relation of Physicians to Dentists and Pharmacists. Several papers of value are promised for this Symposium and the subsequent general discussion will be helpful. 5. A Symposium on—Are Modern School Methods in Keeping with Physiologic Knowledge? There is probably no subject of general interest that should be directed by the medical profession, of more importance than this. Apart from the papers promised, arrangements are being made for a discussion opening up the whole subject from various points of view. 6. In addition to the above, there will be several papers upon independent topics, affording a variety to the program.

Massachusetts Medical Society.—At its meeting on March 23, 1904, the Massachusetts Medical Society, Suffolk District, Section for Obstetrics and Diseases of Women, elected Dr. Daniel H. Craig as its President. On March 24, after presenting a paper for their consideration, Dr. Craig was given an Honorary Membership in the New Hampshire Surgical Club, at its Semi-annual Session, held at Concord, N. H.

Pathological Exhibit at the St. Louis World's Fair.—There will be a pathological exhibit at the World's Fair in St. Louis under the auspices of the American Medical Association. The exhibit, which will be held in the Palace of Education in a gallery over the east main entrance, will be of wide scope, covering the field of general pathology and bacteriology. The President of the Association has appointed the following Exhibit Committee to take charge of the work: Executive members: Ludwig Hektoen, Chicago; A. J. Ochsner, Chicago; W. A. Evans, Chicago; W. T. Eckley, Chicago; L. F. Barker, Chicago. District members: J. N. Hurty, World's Fair; Frank F. Wynn, Indianapolis; Max Herzog, Philippine Islands; V. C. Vaughan, Ann Arbor; W. W. Keen, Philadelphia; J. S. Billings, Jr., New York; Philip King Brown, San Francisco; Ellsworth Smith, Jr., St. Louis; Allen J. Smith, Philadelphia; F. W. Farham, New Orleans; R. M. O'Reilly, U. S. Surgeon-General. Dr. Ellsworth Smith, Jr., who has charge of the St. Louis district, has appointed the following Advisory Committee to assist him in the organization of an exhibit for his district: Drs. Y. H. Bond, H. W. Bond, John Young Brown, B. Meade Bolton, Willard Bartlett, N. B. Carson, O. H. Elbrecht, W. E. Fischel, B. M. Bypes, Bransford Lewis, H. W. Loeb, Robert Leudeking, B. G. Mudd, Henry Schwarz, Chas. Shattinger, J. H. Simon, C. A. Snodgrass, Justin Steer, Hugo Summa, Robert Terry, E. F. Tiedemann and H. Tuholske.

American Institute of Physical Culture.—Jay W. Seaver, M.D., Medical Examiner at Yale University Gymnasium, President of the Chautauqua School of Physical Culture, President of the American Institute of Physical Culture of Boston, and the highest authority on Anthropometry, addressed the physicians of Boston and vicinity, at the rooms of the Institute, 29 Beacon Street, Boston, Mass., on Saturday, March 26. "Exercise," said Dr. Seaver, "may not only be classified as one of the necessities of life, like food and air, but it may be looked upon as a therapeutic means of very high value. Exercise may be divided into two general classes, as active and passive, the first being made up of movements that are directed by the central nervous system, consisting of such movements of the various parts as cause a complete flexion and extension of the joints with the consequent stretching of the muscles that would ordinarily produce these joint movements; and second, the muscles may be subjected to mechanical pressures and kneadings that will stimulate the circulation of both blood and lymph, and produce nutritive changes that are quite similar to those set up by active exercise. These passive movements have been grouped under the term massage. A combination of active and passive movements may be used at times with advantage, the attendant resisting the active movements of muscles in a more or less vigorous manner according to the condition of the muscles that are being treated. The abnormal conditions that are best treated by exercises are those of the nervous system where there is a tendency to inertia and explosive action. The normal working of the motor portions of the brain with the attendant activities of large sensory tracts will treat the entire nervous system by one of those fundamental processes that is so essential to vitality and to the smooth or well coordinated functions of the brain. The utilization of nerve force through these normal channels will usually prevent the explosive action of the nervous system along abnormal lines. One sees a good illustration of this in the restful sleep that follows a hard day's work of physical activity, and the opposite effect in the restless, fitful sleep where the day's work has been of an intellectual character and accompanied by no physical activity that has, so to speak, called the brain back to its fundamental processes."

American Association of Pathologists and Bacteriologists.—This association held its fourth annual meeting in New York on April 1 and 2. A report of the Proceedings will be found in a subsequent issue of the Medical News.

Tenth International Congress of Ophthalmology in Lucerne.—In compliance with the request of numerous foreign colleagues, the date of the Congress has been changed. The official reception of members will now take place in the evening of September 13; the mornings and afternoons of September 14, 15 and

16 will be devoted to scientific work, and on September 17 an excursion will bring the Congress to a close Those colleagues wishing to secure accommodation at Lucerne beforehand, are advised to apply, before September 1, to Dr. F. Stocker, president of the local Committee at Lucerne. He will engage for them rooms at one of the best hotels (early breakfast included), at 5 francs a day each person.

American Neurological Association.—This association has fixed the time of its meeting at St. Louis for September 15, 16 and 17; and this will be immediately followed by the sessions of the various medical departments of the Congress of Arts and Sciences, beginning September 19.

Seventh Annual Meeting of the American Gastro-enterological Association.—This society will meet at Haddon Hall, Atlantic City, N. J., June 6 and 7, 1904. The program will consist of a Symposium on Gastric Ulcer, to be participated in as follows: Introduction, J. C. Hemmeter, of Baltimore, Md.; Bibliography, Charles D. Aaron, of Detroit, Mich.; Pathologic Anatomy, Harlow Brooks, of New York; Pathogenesis, W. G. McCallum, of Baltimore, Md.; Incidence of Gastric Ulcer in the United States, Campbell Howard, of Baltimore, Md.; Gastric Ulcer in Children, E. G. Cutler, of Boston, Mass.; Symptomatology and Course, Max Einhorn, of New York; Atypical Forms, G. W. McCaskey, of Fort Wayne, Ind.; Complications and Sequelæ, M. Manges, of New York; Conditions of Blood and Urine, T. Futcher, of Baltimore, Md.; Differential Diagnosis, H. W. Bettman, of Cincinnati, Ohio; Further Remarks on the use of Orthoform in the Diagnosis of Gastric Ulcer, F. H. Murdoch, of Pittsburg, Pa.; Medical Treatment, S. W. Lambert, of New York; Surgical Treatment, Joseph A. Blake, of New York; Classification of Gastric Ulceration and Hemorrhage, Report of Case of Perforating Angiosclerotic Gastric Ulcer, A. L. Benedict, of Buffalo, N. Y.

OBITUARY.

Dr. John Metcalfe Polk died of pneumonia at the home of his parents, 7 East Thirty-sixth Street, on Tuesday, March 29, at 1.30 A.M. He was the son of Dr. William M. Polk, Dean of the Cornell University Medical College, in New York City, and grandson of Bishop Leonidas Polk, of Tennessee, Lieut. General in the Confederate Army. He was born May 6, 1875, and was graduated from the Sheffield Scientific School of Yale University, receiving the degree of Ph.B. in 1896. He was one of the prominent men in his class and a member of the Delta Psi Fraternity. In the following year he began the study of medicine and was graduated from the Cornell University Medical College in 1899, second in his class. From January, 1900, until January, 1902, he served as interne on the Second Medical Division of Bellevue Hospital, and during the following year took a postgraduate course abroad, chiefly in Vienna. On returning to this city in December, 1902, he was immediately appointed one of the instructors in the Medical College from which he received his M.D. degree and at the time of his death was Instructor in Medicine and in Physical Diagnosis. Last fall his industry, his thorough training and his remarkable clinical abilities won him the position of Adjunct Assistant Physician in Bellevue Hospital. Dr. Polk was a man of attractive personality, unusual force of character and of great promise. During the past winter he had been conducting some experimental work upon the hemolytic action of the blood in infectious disease which his colaborers in the laboratory considered of remarkable value. This had practically been completed when he was taken ill, and it is earnestly hoped that the results interrupted by his death may be collected and published. The loss of so fine a man will be greatly felt by the profession at large, and particularly by the faculty and students of the Medical College; and the large circle of those who know and so highly esteem his father will feel the keenest sympathy with his parents in their great sorrow.

Dr. David McKay died in Dallas, Tex., on Wednesday last. He was born in Glasgow, Scotland, in 1832, served on a British warship as surgeon in the Crimean war, settled in New York, and in 1861 enlisted in the Seventy-ninth New York Volunteers. Six years ago he was made surgeon general of the Grand Army of the Republic.

Dr. A. B. Arnold, for many years well known in Baltimore, is dead at San Francisco. He was graduated in medicine at Jefferson College and was professor of nervous diseases at the Baltimore College of Physicians and Surgeons from 1876 to 1898, when he went to California. He wrote much for medical and literary magazines.

Dr. George H. Butler, of this city, died last week in the sixty-second year of his age. He was graduated from the Bellevue Medical College in 1869, and was a member of many medical societies, including the Medical Society of the County of New York, the New York Physicians' Mutual Aid Association, the New York Academy of Medicine, and the New York Chemists' Association.

Dr. C. M. Garrison died in Salt Lake City, on last Saturday from cerebral meningitis. Before going to Utah, twelve years ago, Dr. Garrison practised his profession in New York City.

Dr. Alfred Duperier died last week at New Iberia, La., the town that his father founded over a century ago. Dr. Duperier was born there in 1826, and was graduated from the University of Michigan. He was an earnest Whig of old, remained a Union man during the Civil War and advised with Lincoln and Sumner about Louisiana affairs. He rendered effective service in the yellow fever epidemics of 1853 and 1867 in southwest Louisiana.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 12.

THE CRUSADE AGAINST CONSUMPTION—THE VENTILATION OF THE HOUSE OF COMMONS—DOCTORS IN PARLIAMENT—A MINISTER OF HEALTH.

On March 10 the annual general meeting of members of the National Association for the Prevention of Consumption and other forms of Tuberculosis was held under the presidency of the Earl of Derby. There was a very scanty attendance. Reference was made in a previous letter to the prevalence of consumption among Post Office employees here. Some of your readers may therefore be interested to know that at the meeting in question it was announced that the Postmaster-General has sanctioned the organization of an effort to raise a fund sufficient for the endowment of 100 beds for employees suffering from consumption. The beds to be endowed are in the Sanatoria erected by the National Committee for patients who, though not well-to-do, are able to contribute something toward the cost of their maintenance and treatment. The fund for the purpose is to be raised by periodical stoppages of pay. The report of the Council showed that the Association is, financially speaking, in a bad way. Indeed the Honorary Treasurer, Mr. Malcolm Morris, stated that if

public support is not forthcoming to a much larger extent than has hitherto been the case, the Association must before long, as Carlyle would have put it, "deliquesce." The report further stated that during the past five years the Council had made strenuous efforts to induce medical officers of health throughout the country to impress on their authorities the advantages likely to follow the adoption of a system of voluntary notification of phthisis. A Select Committee of the House of Commons recently sanctioned a corporation by-law for Sheffield, in which notification of tuberculosis of the lungs is made compulsory on every registered medical practitioner called upon to visit any person suffering from such disease. As to the isolation of consumptive cases in workhouses and asylums, steps have been taken by a few boards of guardians in Great Britain to deal with the question. Considerable progress in the erection of sanatoria has been made during the year, and a new edition of the list of such institutions published by the Association shows that there are now some 70 institutions in the United Kingdom, making a total of 2,760 beds. This is an increase of 18 institutions and 375 beds over the return in October, 1902. The majority of these institutions are, however, for private paying patients, and the need of providing accommodation for the poor consumptive is still extremely urgent. There are at the present time 935 members of the Central Association, and 2,900 of the branches, making a total of 3,835. There are now in the United Kingdom 20 branches of the Association and five kindred associations. During the year new branches were formed at Hereford and the Aberystwith University, which has constituted itself into a separate branch of the West Wales Branch. At the present time a sanatorium for 60 beds is rapidly approaching completion at Winsley, with 40 free beds and 20 beds at an average charge of about 6s. a week. Glasgow is raising funds for the provision of a sanatorium; the West Wales Branch has obtained a site and is appealing for funds; the Leeds Association has a sanatorium for 30 beds; the Devon and Cornwall Branch have started their sanatorium at Didworthy; and the Cumberland Branch has procured a site to build a sanatorium; Paisley and one or two other centers are taking measures to provide sanatoria. In addition to the branches in the United Kingdom, colonial branches or kindred associations have been formed in Canada, Victoria, New South Wales, South Australia, Natal and Cape Colony.

For many years past constant complaints have been made by our legislators of the foul atmosphere in which they have to do their work in the House of Commons. Several committees have been appointed to investigate the causes of the evil and to suggest a remedy. Counsel has been sought of architectural, engineering, sanitary and medical oracles, and large sums of public money have been expended, but the House of Commons has still the reputation of being one of the worst ventilated buildings in His Britannic Majesty's dominions on which the sun never sets (and in some parts of which it hardly ever rises). The air in the House swarms with bacilli of the most ferocious species, and in the state of diminished resistance caused in Members by the vitiated atmosphere in which they discharge their legislative functions, these invisible enemies of the human race find them an easy prey. Some years ago the House was almost decimated by influenza. Is it surprising in the circumstances that our politicians waste their time in interminable wrangles which lead to nothing; if in their speeches Ministers temper ineptitude with irritability, and if the leaders of the Opposition seem to suffer from intellectual asphyxia? The mental state of the House, once called by John Bright the august Mother of Parliaments, may often fairly be described in the words in which the author of the *Dunciad* sings the final triumph of dulness

"And universal darkness covers all."

There is now promise of a better state of things. Various measures suggested by a Select Committee which sat a few months ago are to be adopted. A new ventilating plant is to be installed forthwith. A tunnel which runs from the Chamber to the terrace on the river Thames will serve to harbor a monster fan, driven by a 30-h.p. electric motor. This fan will suck in the fresh air from the terrace, but before reaching the House the air will pass through iron frames covered with the finest copper gauze, and will be cleansed of all impurities by water sprays constantly playing upon the metal mesh. On foggy days the air will probably be passed through cotton wool—a method stated to be remarkably effective in purifying the atmosphere. Before reaching the House the air will be heated and delivered through the perforated stall-boards and a large grating covered with open-work matting in the center of the Chamber. It is estimated that 50,000 cubic feet of air can be introduced per minute. It may be hoped that the effects of an improved ventilation may soon manifest themselves in better legislation. The method of dealing with fog might perhaps find a wider application than was dreamed of by the Select Committee. Poor Oscar Wilde, in one of his plays, expressed a doubt whether it was the fogs that caused the serious people or the serious people that caused the fogs. Seriousness—or to give it its right name, dulness—is so prevalent in our Parliament that its normal condition is to be enveloped in a dense fog. If means could only be devised by which the speeches of most of the Members could be passed through thick layers of cotton wool, a political reform such as it has not entered the mind of any statesman to conceive would be accomplished!

There is a feeling among practitioners of medicine here that both Parliament and the profession would be all the better if the House of Commons contained a larger number of medical members. At present it has scarcely half a dozen, and not one of these can be looked upon as a representative of the great body of general practitioners. It would unquestionably be a good thing for the nation if Parliament had the benefit of the expert knowledge that medical men can bring to the consideration of questions of public health. There are, however, difficulties in the way which are not fully appreciated by the profession. A doctor would have no chance of being elected by any constituency to which he offered himself as such rather than as a politician. In nearly every constituency there is an element—greater in some and less in others—of the foolish hostility to medical men and the science of which they are the hierophants, which appears to be a characteristic of modern democracy. Again, the position of a Member of the British Parliament is one that necessarily involves considerable expense. A contested election costs anything from $3,000 to $10,000. Then every place looks to the M.P. who has the privilege of being its representative to subscribe not only to all the local charities but to the football, cricket, lawn tennis, hockey and other clubs whose name is Legion. A friend estimates that in addition to the extra expenditure caused by the necessity of living a good part of the year in London it costs him about $2,500 a year to represent a small borough. Members for large cities and for counties have to pay a much heavier price for helping to make the laws of a not always grateful country. There are not many men in our ranks who could afford so expensive a luxury as a seat in the House of Com-

mons, and there are practically none in the active practice of their profession who could spare the time required for the proper discharge of senatorial duties. If a medical man takes to politics he is virtually compelled to give up his profession. A suggestion that the British Medical Association should supply the funds required to secure the election of one or two doctors and contribute to their expenses while in the House has found some favor among a certain section of the profession. It is doubtful, however, whether the Association could find the money for such a purpose, and it is almost certain that, even if funds were forthcoming, it could not find the right kind of men. If the sort of person who makes himself most conspicuous as a medical reformer among us were to be sent to Parliament as, even indirectly, a "Member for Medicine," he would simply bring the profession into general contempt.

A step that will help to make the influence of the few medical men who are now Members of the House of Commons more effective was taken on March 8, when a Committee of Public Health was formed to watch all proposed legislation concerning the public health. Dr. Farquharson is the Chairman, and among the Members are Sir Michael Foster, till recently Professor of Physiology in the University of Cambridge, Sir John Batty Tuke, M.D., formerly President of the Royal College of Physicians of Edinburgh, and Dr. Rutherford Harris, the *fidus Achates* of Cecil Rhodes, who is far more financier than physician. Sir Walter Foster, who takes the jumping cat as his political Mentor, at present holds aloof. A movement has been set on foot for the reconstitution of the Local Government Board, which is the Central authority in our sanitary administration, and for the creation of a special Government Department of Health independent of the Board. A committee of which Lord Jersey is chairman has the whole question under consideration. The opinion of the medical profession was expressed the other day by Sir John Batty Tuke, who said: "I am distinctly in favor of a Ministry of Health, and I would have it possessed of strong powers; and I think we shall see a change for the better in our medical administration before long."

TYPHOID FEVER AND CONTACT.

To the Editor of the Medical News:

Sir: The importance of the subject, coupled with its comparative newness, warrants me in this final demand on your courtesy, in the discussion of the part played by "contact" in the dissemination of typhoid fever. The letter from Prof. Vaughan in your issue of March 19 summarized in a masterly citation the conclusions of the special commission which investigated the spread of typhoid fever during our recent war, and shows conclusively, as he states, that the fever, as it prevailed in the national encampments, was disseminated not to any large extent by drinking water, but chiefly by contact. This is a service for which the profession cannot well be too grateful to Reed, Vaughan and Shakespeare, and which has been quite generally acknowledged, as witness the 1903 edition of Osler's Practice. There are, however, one or two statements in Prof. Vaughan's letter on which I think it incumbent on me to take issue, notwithstanding the fact that he based his remarks chiefly on your editorial and not on my article. The brunt of the matter is borne by the final paragraph of his communication, in which he says: "Now, Mr. Editor, I think I am not too positive when I say that whatever Bretonneau or Trousseau may have thought, or whatever Koch propounded 'more than a year ago,' the fact that typhoid fever is spread largely by contact was first demonstrated by American observers." This, I feel, is hardly fair, either to the earlier French observers or to Koch. The theories of Bretonneau and of Trousseau were not mere haphazard notions or suggestions, but represented the only possible conclusion to be drawn from the study of a very large number of accurately and carefully observed epidemics. In the classical work of Trousseau (*Clinique Médicale de L'Hotel-Dieu de Paris*, 1867) more than five pages are given to the elucidation of this theory, and a large number of epidemics are analyzed from the reports of other observers, with the result that no unprejudiced reader can fail to be convinced of their bearing. Says Trousseau, "An analysis of the reports on the typhoid epidemics in the provinces of France, which are yearly presented to the Academy, demonstrates the contagious nature of typhoid fever definitely for all time." And again, summarizing his conclusions as special commissioner on the epidemics of 1857: "Once started, the disease is propagated by a series of transmissions which are sometimes easy, sometimes impossible, to trace." One must, however, read the entire chapter to appreciate how thoroughgoing and logical were the conclusions of this great school of Bretonneau's. It is then hardly just to say that "the fact that typhoid fever is spread largely by contact was first demonstrated by American observers."

The chief point, however, on which I would differ with Prof. Vaughan is his evident identification of this undoubted fact of contact infection, with the recent theory of Robert Koch. The American commission demonstrated that under certain conditions, namely those maintaining in the national encampments, typhoid fever was spread chiefly by contact. The theory of Koch, however, is so much more comprehensive and far-reaching that it cannot in any way be connected with their work; indeed, it may far more logically be regarded as a true descendant of the tenets of the French school, which held that all epidemics were so propagated. Koch believes (1) that for all *practical purposes* the typhoid bacillus may be regarded as an obligate parasite, which cannot under ordinary circumstances maintain its existence for any length of time in streams or wells. (2) That the vast majority of typhoid infections or epidemics are due to the mediate or immediate transmission of the germs of the disease from the person of one victim to the intestinal tract of the next. The ways in which this may happen were illustrated in my letter. (3) That prophylaxis must be reconstituted on an entirely new basis, with the early identification of the ambulant cases of typhus levissima, and the surveillance of all cases as long as stools or urine (Piorkowski) are infected. I fail to see that the American commission in any way anticipated this "Theory of 'contact infection' in typhoid fever."

Finally, I believe you were justified in pointing out that this theory of "contact infection," as elaborated by Koch, is foreign to Americans, although the fact is well understood that transmission by contact under certain conditions, notably such as maintain in army encampments, does occur. Thus Osler, on page 5 of the Practice, 1903, states: "Infection of water is unquestionably the most common mode of conveyance;" but "the possibility of the direct transmission through the air . . . must be acknowledged." Again, on page 2, he emphasizes the water supply and drainage as the general factors in the dissemination of the disease, and instances the encampment epidemics as special examples of supposed contact infection.

I hope I have made clear the historical relationship of these various contributions to typhoid epidemiology.

Like everyone else, I regard the work of the American commission as a model of exact observation and logical reasoning. But I cannot, nevertheless, depreciate the earlier French work, or the more recent advances made by Koch. Respectfully, R. Weil.

March 22, 1904.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held January 23, 1904.

The President, Frank M. Daniels, M.D., in the Chair.

Some Cases of Genito-urinary Affections, with Involvement of the Kidneys.—The scientific business of the evening was opened by Dr. Eugene Fuller, in a description of some of these affections. He said that undoubtedly the bacteria coli not infrequently find their way through the kidneys into the bladder where they are the source of inflammatory conditions of various kinds. In these cases it is important that the bladder should have thorough drainage. Some of the cases when they almost look hopeless, give brilliant results under thorough drainage of the bladder, but they die very easily of septicemia, and the greatest care must be exercised not only immediately after the operation, but for a considerable period. In a case under his care not long since, the patient had been drinking hard for some time, and while suffering from delirium tremens had also some retention of urine. It was always a struggle for him to get his bladder emptied and there was more or less residual urine, but this led to a very severe attack of cystitis with absorption of septic material.

Backward Infection.—In this case there was so much albumin and casts in the urine, owing to the fact that an upward infection of the kidneys had taken place from the bladder that a very prominent physician had given the patient up as suffering from chronic Bright's disease in a hopeless stage. He had nearly died on several occasions from edema of the larynx and there was little expectation of saving his life. Perineal section was performed, however, and thorough drainage established. Delirium tremens developed after the operation and the patient was encouraged to drink as much as possible of water in order to keep his kidneys thoroughly flushed out and also to get rid of the alcohol accumulated in the system. After a time this case improved so much that a very good prognosis seemed possible. In the course of time the urine became perfectly clear and entirely free from casts and albumin. It seems not improbable to Dr. Fuller that in a certain number of the cases of diagnosed chronic Bright's disease the affection is really primary in the bladder with a secondary infection of the kidneys, and if the kidneys are allowed to do their work properly without further irritation the supposed Bright's disease disappears, or becomes a comparatively unimportant factor in the case. These are the cases of Bright's disease that live for many years notwithstanding the bad prognosis given by their physicians.

Uremic Symptoms Due to Bladder Conditions.—In another case recently under Dr. Fuller's care there were many symptoms of uremia and the fatal termination was looked for as a near event. A stone was found to be present in the bladder, however, and considerable inflammatory reaction. In this case there had evidently been backing up of the urine into the kidneys, for the ureters on operation were found so dilated that the tip of the forefinger could be passed into either one of them. The specific gravity of the urine in this case was from 1.002 to 1.003, and it hardly seemed possible to save the patient. The stone in the bladder was found to have formed in a pouch behind an enlarged prostate. Because of this complication of conditions it was considered necessary to establish drainage, both above the pubis and in the perineum. Immediately after the operation polyuria set in as a critical symptom of the patient's condition. Some writers say that patients who thus suffer from polyuria with a low specific gravity never recover. This patient, however, had a good stomach and could take fluids in large quantities and when he refused to drink, a vein was opened and 1,500 c.c. of normal salt solution were injected. This was repeated several times, but when the refusal to drink continued, a mouth gag was put in, a stomach tube inserted and a quart of water was poured into the stomach. This patient recovered perfectly, though he still requires a physician's care to prevent complications, having to avoid excesses of any kind.

Pseudo-uremia.—In another case of apparent uremia there were many head symptoms pointing to a urinary intoxication. These had been noted for some time. Under drainage of the bladder the patient recovered completely and now has been perfectly well for nearly a year. He still needs careful nursing and regulation of his diet and living conditions or there may be a relapse. Not infrequently these cases are allowed to leave the hospital too soon after operation, with the result that they suffer from complications and sequelæ of their previous uremic condition. In a recent case a doting daughter thought that she could manage her father better than a nurse and so, eight weeks after operation, she was allowed to take the old gentleman home. A few weeks later he died suddenly from pneumonia, probably as the result of too great indulgence on the part of his nurse in allowing him to expose himself in changeable weather.

Careful Nursing.—Dr. Howard Lilienthal said that he agrees with Dr. Fuller that some of these patients suffering from cystitis with secondary kidney conditions are often helped by surgical intervention, even when their pathological conditions were apparently hopeless. With regard to drainage he has come to realize how important this factor may be in making the result of operation on the bladder more successful. In a case exhibiting uremic symptoms with tendency to polyuria, but having cystitis and an enlarged prostate he has removed the prostate and lost the patient, when, if thorough drainage had first been established, a fatal termination would probably not have occurred He has not always found it necessary to secure drainage by surgical incision into the bladder, but has found that proper preparation for operation can be effectually secured by catheterization of the patient every three hours, day and night, for several days before operation. This gets rid of the bacteriuria and the often more or less pea-soup-like urine of the patient becomes perfectly clear.

Perineal Drainage.—In Dr. Lilienthal's opinion perineal drainage adds an element of danger to the case. The urine is allowed to come in contact with planes of muscles in the perineum which may easily permit infiltration of the surrounding tissues. On the other hand, suprapubic drainage, if carefully accomplished by means of siphonage in the hands of attendants who are familiar with this method of drainage, leaves none of the risks of insidious infiltration of urine that may occur when the perineum is opened.

Dr. Frederic C. Curtis said that in his hands perineal drainage has always seemed to give better results. He believes that many so-called kidney diseases are really not primary nephritis, but secondary infections of the

bladder, due to the backing up of infected urine. These infections are often from the urethra up and not from the kidney down. Perineal drainage is certainly better than trying to retain a catheter constantly in the bladder for purposes of drainage, since this so often proves a source of irritation. Very frequent catheterization in those patients whose bladders are already of very low resistive vitality is apt to set up serious infections of various kinds. The most careful cleansing of the catheter leaves still many bacteria in the urethra to be carried back into the bladder. It must not be forgotten that kidneys have sometimes been extirpated with the idea that they were primary surgical kidneys, when they were really secondary infections.

Suprapubic Drainage.—Dr. Robert H. Green said that in his experience for chronic conditions of the bladder, suprapubic drainage is better than perineal drainage. There has been a tendency to overdo perineal drainage. In tuberculous conditions within the bladder this is especially true. More care must be exercised, however, to keep up suprapubic drainage. The nurses who take care of the patient must be used to this form of treatment so as to be able to keep the skin from getting infected or even irritated, for this forms a favorable nidus for the growth of bacteria and exposes the patient.

Dr. Follen Cabot said that the most important thing with regard to serious bladder and other genito-urinary conditions is careful treatment after operation, carried out over a long period. The route of drainage does not make so much difference as the method of treatment afterward.

Dr. Fuller, in closing the discussion, said that frequent catheterization, with the idea of emptying the bladder of infected urine, will not avail much if the prostatic condition present be serious. For milder cases it does very well and is to be commended. Where there has been retention of urine over a long time it is a useless waste of time to attempt to clear up the urine by means of catheterization.

New Cystoscope.—Dr. Follen Cabot presented a new cystoscope. This has many advantages over previous instruments. For instance, after the ureters have been catheterized, the cystoscope may be withdrawn, leaving the catheters in place for five or six hours, if necessary. If the urethral instrument is allowed to remain for more than a half hour, patients usually become very restless. Some patients become intolerant of it even before this length of time has elapsed. The oval shape of the cystoscopic tube in Dr. Cabot's instrument gives more room for the same size of caliber and is better for a contracted urethra, especially for such contractions as occur near the meatus.

Colon Bacillus in the Kidney.—The paper of the evening on this subject, was read by Dr. Robert H. Green. He said that he did not mean to have any reference to surgical kidney. Twenty years ago it was thought that the knowledge of nephritis was pretty accurate and that its diagnosis could be made from urinary examination. Notwithstanding this, however, uremia followed by sudden death, sometimes occurring without any urinary symptoms. Often, however, small abscesses were found to be present in the kidney in these cases. In recent years it has come to be realized that many bacteria find their way into the urine without injury to the kidneys, and this has been found to be especially true of the *Bacillus coli communis*.

Confusing Methods of Treatment.—A number of methods of treatment for nephritis have been suggested which, far from proving helpful, have tended rather to confuse the practitioner. A number of drugs have been vaunted as good for nephritis or preventive of the occurrence of bacteria in the urine. Decapsulation of the kidney has been advanced as a cure for nephritic conditions. The tearing off of the capsule, however, is likely to do more harm than good, since it exposes patients to the danger of infection from whatever bacteria may be present. Not much dependence can be placed on drugs and even such as widen the caliber of the blood vessels or that increase blood pressure and consequently bring more blood to the kidney can be depended on to do good. In these cases the source of the bacteria that find their way into the urine from the kidney and that sometimes cause kidney symptoms is not always easy to determine, but seems to be due to an ascending affection.

Illustrative Cases.—Dr. Green described as his first patient a man who, on attempting to pass a life insurance examination, was rejected because of the presence of albumin and casts. The rejection was not absolute, but the man was told that he could not be accepted unless his urine could be cleared up. The family history was good, though the man himself had suffered from two attacks of gonorrhea. His urine was found to contain colon bacilli in large quantities in almost pure culture. He refused to allow the use of a cystoscope, so the Harris segregator was employed, but it was found that the bacteria came from both kidneys. On a carefully selected diet, especially with laxative effects from plenteous fruit consumption, his urine cleared up somewhat. In a word, when his digestive disturbances improved his urinary condition was also ameliorated. In the man's history there was an attack of severe dysentery during which it was possible that intestinal walls might have become so affected or so adherent that the outward wandering of colon bacilli became possible. The second case was also an insurance case and was refused because of the presence of albumin, though the man's general health was good, his habits were excellent and he led a very regular life. He denied gonorrhea, yet a number of colon bacilli of the ordinary type could be found in his urine. Under medication his urine cleared up to some extent. Such cases are not very rare in the literature at the present time and for the last decade cases have been reported in which a considerable number of bacteria found their way into the urine without there being any definite lesion of the kidney.

Cases from the Literature.—Not long since Nichols collected about 45 cases of bacteriuria, thirty of which were apparently colon bacilli cases. The presence of colon bacilli is nearly always associated with albumin in the urine, though with no other symptoms of kidney trouble, hence the frequency with which such cases are rejected by life insurance companies. In practically all of these cases the use of antiseptics in the intestinal canal does good. In fact this seems to be the only way by which the conditions can be improved.

Transitional Stage in Kidney Pathology.—Dr. Reynold Webb Wilcox said that this consideration of bacteria and albumin in the urine without kidney involvement can not but be valuable. At the present moment one of the great difficulties of the diagnosis of kidney disease is the recognition of the capacity or incapacity of the organ to do its work. At the present time there is a traditional stage in kidney pathology in which the old idea of chronic inflammation in chronic nephritis is being displaced by the notion of degeneration from autointoxication. Chronic interstitial nephritis is very different from acute interstitial nephritis, hence it has come to be considered better to talk of chronic arterial nephritis. When chronic arterial nephritis is present there is no reason *a priori* why decortication of the kidney should do good. There are

many infections of the kidney that are not taken cognizance of in text-books. It is known now that in 20 per cent. of the cases of typhoid fever, typhoid bacilli are found in the urine. While it remains a question whether bacteria may pass through an absolutely uninjured kidney there seems no doubt that in a certain number of these cases at least, some pathological condition is produced.

Segregation of Urine.—Dr. Follen Cabot said that for the collection of urine from either kidney, in order to determine the presence of kidney disease, the Harris or Down segregators are not reliable. Sources of error may constantly occur, but cannot be foreseen, and that may lead to operative procedures not justified by the condition really present. In using the Harris segregator he once made a serious mistake where the affection present was not one of either kidney, but of the bladder.

Ascending Infection.—Dr. Fuller said that many of these anomalous conditions in the urinary tract do not begin from the kidney and go down, but begin in the bladder and ascend. Even when the colon bacillus is the cause of a pathological condition of the kidney the germ has usually found its way from the colon into the bladder and thence up to the kidney. Good drainage of the bladder therefore is the best possible prophylaxis of further damage to the urinary tract. When women are suffering from uterine troubles it is possible that germs from the interior of the uterus may find their way into the bladder because of certain anomalous or acquired lymphatic connections between the two organs. Experimentally it was shown a few years ago that when germs are injected into tissues surrounding the bladder, they succeed in finding their way into the bladder in a few hours. This is true if the bacteria succeed in getting into the peritoneum at all. It is probable that in many cases of intestinal disease followed by adhesions a passage of germs from the intestine to the bladder is not impossible.

Dr. Spooner said that there is a larger number of these cases of bacteriuria than has formerly been thought. They are often the cases of pseudonephritis in which the discovery of albumin in the urine leads to the diagnosis of Bright's disease, yet, with reasonable care, the patient lives on for many years, without serious derangement of health.

Frequency of Bacteriuria.—Dr. James J. Walsh said that it is very evident now from the literature of the subject that even virulent bacteria may pass through a healthy kidney without producing serious damage to the kidney structure. Even in such mild affections as a felon or in small abscesses staphylococci find their way into the circulation and thence through the kidney into the bladder. Recent reports with regard to typhoid fever seem to show that in about one-half the cases bacteria occur in the urine and continue to be found there sometimes for many weeks or even several months after convalescence has been established. Whenever there have been severe affections of the intestine, especially if these have been followed by adhesions in the neighborhood of the bladder, bacteria find their way through the intestinal and then the bladder walls of the urine.

Kidney Decortication.—Dr. Walsh said that while in theory the stripping of the capsule from the kidney seemed rather to be contraindicated than recommended, a certain number of cases had been reported in which there was no doubt that good had been done. From the cases so far collated it would seem that especially in young persons suffering from the effects of nephritis following scarlet fever or some of the infectious diseases of childhood was improvement likely to take place.

Ubiquity of Colon Bacillus.—Dr. Frank H. Daniels said that the colon bacillus seems to occur in many parts of the human system. They are natural inhabitants of the colon, but scarcely any organ fails to be visited by them. They are very common in the bladder, they are often found in the biliary passages and in the gall-bladder; they have been found in the pancreatic duct and, in Dr. Daniels' own experience, have been known to occur in the mouth. Just how they got there is not easy to say. It impresses the necessity, however, for great care of cleanliness whenever patients are suffering any affection of the intestinal tract.

Dr. Green, in closing the discussion, said that he is not an advocate of the Harris segregator and he used the apparatus only because his patient refused to have his kidneys catheterized by any of the ordinary methods with the cystoscope. He has, however, often found the use of the urinary segregator of great importance and one of its decided advantages is that it causes no pain. After all, many sensitive individuals are utterly unable to bear the discomfort of having a catheter inserted and then allowed to remain for some time and not infrequently the use of the urinary segregator is sufficient for the diagnostic purposes intended. In the cases under discussion those of bacteriuria, it is not often necessary to secure urine from the separate kidneys, as the affection causing the presence of the bacteria extends to both sides of the urinary tract as a rule, or else is confined to the bladder itself.

Officers.—The election of officers for the ensuing year then took place. Dr. Augustus S. Knight being elected President; Dr. J. Hilton Waterman was re-elected Secretary, and Dr. Joseph H. Kenefick was re-elected Treasurer.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held March 7, 1904.

Arthritis Deformans.—Dr. McCrae exhibited three medical cases. The first was a patient showing the early acute stage of arthritis deformans which in the Johns Hopkins Hospital is thought, in all probability, to be an infectious disease—its late manifestations being too often considered, and its early non-degenerative form being overlooked. Patient was a man of twenty-one years, in perfect health and with good previous history. In December, 1903, he had first noticed creaking and slight pain in the knee. There was also some pain and disability in the other knee, the ankles, the shoulder and the fingers. General health was excellent and most of the joints cleared up leaving behind a somewhat thickened capsule, slight creaking and a little restriction of motion. At present the right knee is the only joint much involved showing fulness, creaking and a thickening of the capsule. The ankle and shoulder, however, are somewhat affected. There is general glandular enlargement, with enlargement of the spleen, increase in the reflexes, normal blood count and no temperature. X-ray picture shows no bone changes. The condition was thought to be probably infectious or at least the result of an infection and probably identical with the disease described by Still. The cases of arthritis deformans studied in the Johns Hopkins Hospital form a complete series according to the age of the patients. In the young cases the glands and spleen are often enlarged and in these patients a diagnosis of Still's disease is made. With increase in age glandular enlargement becomes less marked and we gradually approach the typical arthritis deformans of adults. The disease is, however, the same condition throughout, its manifestations being somewhat altered by the age of the patient. The prognosis of these cases varies. Some of the pa-

tients get entirely well, but in others the disease is recurrent and in many becomes chronic. Two theories as to the nature of arthritis deformans have been advanced, one regarding it as a specific infection and the other as a joint involvement following other varied infections (gonorrhea, influenza, etc.). Certainly in these patients the joint troubles are stirred up by subsequent infections. The question of the local treatment of the joint involved is a most important one, and the value of a good functioning knee joint makes it doubly important in cases where that joint is involved. Arthrotomy and irrigation seem wise procedures and, if a villous arthritis is found, the superabundant tissue can be removed surgically. The important point to remember in connection with this case Dr. McCrae thought to be the fact that the acute stage is so often either overlooked or confused with rheumatism.

Tumor of the Parotid Gland.—Dr. Cole showed this case. There was a distinct luetic history, and five years previously tuberculous glands had been removed from both sides of the neck. A pleurisy eight weeks before admission and a few crackling râles pointed to possible tuberculous condition in the chest. In the parotid region there was a fluctuating superficial swelling which had first appeared without pain six weeks ago. A dram of pus was withdrawn, but no tubercle bacilli were found and cultures were negative. The history of tuberculosis, however, and the clinical characters of the swelling pointed to its probable tuberculous character, though the guinea pig injection had not positively decided the question. Tuberculosis of the parotid is a very rare condition. Certain organs in the body seem to be immune to this infection, the salivary glands being very rarely affected in spite of the fact that the lymph glands are so often involved.

Eosinophiles During Experimental Trichinous Infection.—Dr. Opie read this paper. The eosinophiles were known long before Ehrlich, but the granules were thought to be fat. They occur in all mammals and are always less in number than the neutrophilic cells. The ordinary leucocytosis is well understood, but eosinophilic leucocytosis has never been well worked out. Dr. Opie infected guinea pigs with trichinous meat and found that the eosinophiles showed no change until the tenth or twelfth day and then gradually increased till the twenty-first day. The polynuclears also increased for a time. When a great number of trichinæ were used the weight of the animal fell. Just before death there is a rapid decrease in the eosinophiles. The question of the relation between the blood cells and the course of the embryos in the body is an interesting one. In the mucosa of the intestines there is no definite increase in the eosinophiles, nor is there an accumulation anywhere else except in the lymph glands and in the lungs. In the bone-marrow of animals dead of this disease the fat is found much diminished and the narrow cells increased. This is particularly true of the eosinophiles and the increase affects chiefly the myelocytes. This corresponds to the "leucoblastic marrow" seen in human beings. When the trichinous infection is large, destruction of the eosinophiles is seen and the effects of this parasite, as seen in Dr. Opie's experiments, suggests the work of some soluble toxine.

Chemical Origin of the Leucocyte in Leucemia.—Dr. Schmoll reported his investigations on this subject. The blood was studied with the patient on various diets and it was found that food rich in albumin increases the number of leucocytes, the kind of albumin being apparently indifferent. The conclusion was drawn that the body is capable of extracting nuclein from the ingested food and that the increase of phosphorus is an important factor.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section on Clinical Medicine.

Stated Meeting, held March 4, 1904.

Tracheal Tumors.—Dr. Rosenheim read this paper, reporting a case which had occurred in the surgical wards of the Johns Hopkins Hospital. The condition is a rare one, of 3,120 tumors reported in the upper respiratory tract only 7 occurring in the trachea. This lack of susceptibility of the trachea to new growths is probably due to its functional passivity. Dr. Rosenheim's patient was a woman aged twenty-three years who complained of difficulty in breathing. Nine months before admission she first noticed a heavy, choking sensation in the air passages, and cough, dyspnea and slight expectoration soon appeared. Cough without expectoration was present on admission, no glands were palpable and heart and lungs were negative. Laryngoscopic examination showed normal larynx and vocal cords; but just below the cords was a small, red, smooth tumor which did not move with respiration or phonation. Operation was done by Dr. Halsted. A preliminary tracheotomy being the first step in the procedure. The tumor was found opposite the cricoid cartilage and the upper tracheal rings. The patient stopped breathing during the operation but anal dilatation was successful in stimulating respiration. Recovery was uneventful and the patient was perfectly well six months later. The tumor was capsulated, contained mucoid fluid; on section it showed trabeculæ with colloid in the intertrabecular spaces. Pathologically the diagnosis was colloid fibroadenoma.

Tracheal tumors are clinically all alike. They were first seen laryngoscopically by Turck. Of the benign neoplasms all types occur—papillomata, fibromata and chondromata being the most frequent. Carcinoma and sarcoma are the types of malignancy most often met with. On the posterior wall of the upper and lower portions of the trachea tumors are most frequently seen. Of the infectious granulomata lues is the most frequent form; but tuberculous tumors are also sometimes seen. Another type of tumor in this region consists of the proliferations which occasionally occur after tracheotomies. Thyroid tumors are not unusual, are seen most often in women and consist of typical glandular tissue. Bruns and others hold that they represent merely an embryonic misplacement; but Ziemssen claims that they are due to thyroid proliferation and actual in growth involving the trachea. The symptoms of tracheal tumor only occur when stenosis is present. Dyspnea is first to appear. Then comes enfeebling of the voice with hoarseness. Lung changes (bronchiectasis, bronchitis, atelectasis) may occur. The diagnosis is positively made by laryngoscopic or tracheoscopic examination; but, excluding esophageal and thyroid tumor, a husky voice is most suspicious, provided there be no aortic aneurism. The nature of the tumor is practically impossible to be sure about. Prognosis is, without operation, most unfavorable. The tumor may be removed by laryngotracheotomy or by endotracheotomy.

Hysterical Paralysis in Men.—Dr. Thomas reported two cases of this affection. Hysteria, on account of its frequency in women, is easily overlooked in the opposite sex; but it does occur and with some frequency. The first patient was a farmer and banker, who had led a more or less sedentary life since his eighteenth year. He had always been bothered by constipation with occasional attacks of abdominal pain and vomiting, which he attributed to nervous dyspepsia. For this he was treated at the Johns Hopkins Hospital and was discharged well. He was in the next few months somewhat overworked and suffered three severe nervous

attacks. A little later he was taken with pain in the left side, diagnosed pleurisy. He became well from this attack, but his body was afterward drawn over to the left side. Soon after an area of numbness appeared in the left hip, the left leg began to drag, and a fourth nervous attack supervened. Patient was admitted with pain in the left side, subjective numbness, paralysis of left leg below the knee. On the inside of dorsum of foot there was an area where touch and pain sensations were diminished (pressure on the sciatic nerve was thought of, but the anesthesia was on the wrong side of the foot). Reflexes were normal, and the foot was held up when electricity was applied and the current shut off without the patient's knowledge. He walked dragging his toe. Treatment was electrical and psychical, and the patient soon got perfectly well. The second case was a young man of twenty years, who, while romping one evening, received a slight injury to his arm with a good deal of shock. A large amount of whisky was given to treat the shock; and the following day there was great pain in the right arm, absolute paralysis appearing twenty-four hours later. An injury to the brachial plexus was of course diagnosed. When first seen by Dr. Thomas, patient showed absolute powerlessness of the arm with complete anesthesia to pain, touch and temperature extending to the wrist where it ended sharply. Muscular sense was wanting in the same area. Paralysis affected the shoulder and arm, but there was slight movement of the fingers. Reflexes and electrical reactions were normal, which, together with the distribution of paralysis and anesthesia, placed organic disease out of the question. Electrical treatment was given. On the second day recovery had occurred as far as the elbow, and on the fourth day patient was perfectly well. In connection with these cases Dr. Thomas referred to the suggestion of one of the European observers that the hysterical stigmata may be due to suggestion, and emphasized the importance of avoiding questions which may give the patient a clue as to what symptoms he *ought* to present.

Dr. Hirschberg said that he had recently seen a case of hysterical mutism in a young man of eighteen years, who had recovered completely in three weeks.

BOOK REVIEWS.

Organic and Physiologic Chemistry. A Manual for Students and Practitioners. By Dr. A. McGlannan, Associate Professor of Physiological Chemistry; Instructor in Clinical Laboratory, College of Physicians and Surgeons, Baltimore. Lea Brothers & Co., New York and Philadelphia.

This is a recent member of the medical Epitome Series of the house of Lea Brothers, and is a most excellent and handy volume. For the beginner such epitomes are often very useful and this is one of the best of the class. It is also serviceable for the old-time graduate who is not quite sure of the differences between a paraffin and an olefine, a fatty acid or an aldehyde. He can find here a short, succinct summary of the principles of organic and physiological chemistry.

Bacteriology of Milk. By Harold Swithinbank, of the Bacteriological Research Laboratory, Denham; and George Newman, M.D., F.R.S.E., D.P.H., Medical Officer of Health of the Metropolitan Borough of Finsbury. E. P. Dutton & Co., New York.

Were one only partly en rapport with the immense importance of the subject of the bacterial flora of milk the suspicion would be engendered that this volume of 604 pages, and encyclopedic in proportions, is not justified; but to the health officer, the practitioner who sees sick children, and those who come in contact with dairy interests, will give a leap of anticipation, that finally this subject, of paramount importance, has been adequately presented.

The hope they will find, we believe, to be fulfilled. The volume is one of the best types of a sanitary exposition of the whole subject of the relation that bacteria bear to milk and the dairy, not to speak of the important consideration given to the problems of milk infections in human pathology.

We welcome this volume, and trust that an appreciative public will render work of this character profitable to both publishers and authors alike. It is largely by such support that our best gifts in medical sanitation have been given, and it is a duty as well as a privilege to encourage the production of work of this enduring and practical type—moreover profit is ample to the purchaser who reads.

General Pathology. By Ernst Ziegler. Translated from the Tenth Revised German Edition and edited by Alfred Scott Warthin, Ph.D., M.D., Professor of Pathology and Director of the Pathological Laboratory in the University of Michigan, Ann Arbor, Michigan. William Wood & Company, New York.

Were it not for the fact that the merits of Ziegler's pathology were so well known to the medical public of this country, we would be inclined to rhapsodize concerning its excellence of form, and generalize upon the philosophical grasp of the subject of pathology, as shown by the author. The subject warrants eulogy, and is deserving of special attention, for, in the new edition, Ziegler is not only translated but interpreted and that means much for the type of work before us. At least eleven editions of Ziegler have come from the Fischer Verlag, and this is, if the reviewer remembers aright, the third English presentation.

We are firmly of the opinion that this type of work should be in every student's laboratory, and every progressive physician's library. Details may change, but the large outlines of pathology, as drawn by Ziegler, will not be materially modified for some time, and the wealth of bibliography will render such a work one of invaluable aid. The publishers have done their part in aiding Dr. Warthin's interpretation.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Infant Feeding in its Relation to Health and Disease. By Dr. Louis Fischer. Third edition. 8vo, 358 pages. F. A. Davis Co., Philadelphia.

Clinical Lectures on the Nervous System. By Sir Wm. Gowers. Second series. 8vo, 250 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

The Treatment of Fractures. By Dr. C. L. Scudder. Fourth edition. 8vo, 534 pages. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

Modern Surgery, General and Operative. By Dr. J. C. DaCosta. Fourth edition. 8vo, 1,000 pages. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

A Laboratory Manual of Physiological and Pathological Chemistry. By Dr. E. Salkowsky. Translated by Dr. W. R. Orndorff. 8vo, 263 pages. Illustrated. John Wiley & Sons, New York.

ORIGINAL ARTICLES.

TUBERCULOSIS OF THE SPINAL CORD, WITH REPORTS OF CASES OF TUBERCULOUS MYELITIS AND OF TUBERCULOUS PACHYMENINGITIS.

BY CHARLES L. DANA, M.D.,

AND

J. RAMSAY HUNT, M.D.,

OF NEW YORK.

TUBERCULOSIS of the spinal cord occurs in five different ways; (1) as part of a general disseminated tuberculosis; (2) as part of tuberculous cerebrospinal meningitis; (3) as tuberculous tumor; (4) as a tuberculous softening or myelitis; (5) as extradural tuberculosis or tuberculous pachymeningitis with necrosis and edema of the spinal cord.

1. A few miliary tubercles are usually found on the spinal pia in general disseminated tuberculosis, but they have no clinical importance.

2. The same statement applies, as a rule, to the involvement of the cord in ordinary cerebral tuberculous meningitis.

3. Tuberculous tumors stand second in frequency among spinal tumors, but since such tumors are themselves very rare, tubercle of the cord is also a relatively unfamiliar phenomenon.

4. *Tuberculous myelitis* is not yet recognized as a separate pathological process by neuropathologists. At least it is not described by Flatau and Jacobs in their recent six-volume treatise on neuropathology; nor referred to by writers on general pathology. I shall hardly pretend that I am furnishing convincing proof of its existence. Yet the following cases are certainly suggestive of it. I know also that some years ago when tuberculous and chronic organic nervous cases were placed indiscriminately together in the Montefiore Home Dr. B. Sachs and myself several times noted the sudden onset of acute myelitic softening in some of these nervous cases and we independently came to the conclusion that it was due to a tuberculous infection.

Tuberculous meningomyelitis is recognized, but here it is only an extension of the process in the ordinary cases of extradural tuberculosis. In my case it seems that there was a direct infection and infiltration of the cord alone.

Case of Tuberculous Myelitis and Softening of the Spinal Cord.—The patient was a man, aged forty years, who was admitted to Bellevue Hospital, suffering from a progressive amyotrophic lateral sclerosis. This began with symptoms of paralysis and spasm in the tongue, extending thence to the arms, and from there down to the hands. The disease had lasted about six months when the patient developed suddenly a fever, and in a few days a complete paraplegia with some involvement of the arms. He died in the course of a week after these acute symptoms.

Post mortem, the spinal cord was found to be softened from the level of the first dorsal cord to the third cervical segment. There was no apparent tuberculosis found elsewhere, but I cannot say that the examination was very complete. The meninges and vertebræ were normal. The softening was so extensive in the mid-cervical portion that the cord could not be preserved. Beginning at the level of the lower portion of the lesion, that is, the first dorsal segment, there was seen upon transverse section a round white area in the posterior column of the cord. Sections made successively through the dorsal cord showed that this white pultaceous area extended down to about the middle of the fourth dorsal segment of the cord, growing smaller as it extended down. In the first two or three segments of the spinal cord, there was also a superficial softening of the anterior part of the lateral columns of the cord upon the right side. There was absolutely no sign of hemorrhage in the cord when it was examined in its fresh state. Even at the lower point of the white and softened substance, there was no redness or sign of extravasation. The cord was hardened in Müller's fluid, except a small portion which included some of the softened area. It was placed in alcohol, and was examined for me by Dr. H. T. Brooks, of the Post-Graduate laboratory. He found tubercle bacilli in it, and there could be no doubt but that the acute necrotic process which had attacked the cord, was one of tuberculous infiltration and softening. An examination of the spinal cord later, under the microscope, showed also that the necrotic process was not accompanied with any hemorrhagic process, and that there was a little inflammatory reaction. Examination of the affected area showed disintegrated nervous tissue. This case was, therefore, one of progressive amyotrophic lateral sclerosis in the first place. Superimposed upon this was an acute tuberculous infection and also softening of the previously diseased spinal cord. One form of the extension of this softening took the shape of a perforating necrosis, which extended down through the posterior column. A less marked development of this was a superficial necrosis which affected part of the anterior and lateral columns.

This case suggests, to my mind, that the perforating necroses which accompany some severe cases of myelitis or cord degeneration, are really tuberculous phenomena, and not primarily hemorrhagic, although, in some instances, there may be a hemorrhagic process associated with it.*

* The clinical features have been described in detail by Dr. Jos. Collins, American Journal of the Medical Sciences, June, 1896.

5. *Tuberculous pachymeningitis* from caries of the vertebræ, with so-called compression myelitis, is the affection most commonly met with and of most practical importance. When the process extends from the bone to the extradural space, this becomes filled with a tuberculous, caseous, and sometimes purulent, mass, which surrounds the cord; the cord then becomes secondarily affected, and its functions interfered with; and we have the symptoms of "compression myelitis." There is not always, perhaps never, a true mechanical compression of the cord through the bending of the spinal column. The compressing mass, however, interferes with the vascular and lymphatic circulation. As a result, there is sometimes an ischemia and sometimes an edema, or both, with the result that the cord may undergo degeneration and necrotic softening. If the process continues, the parts are destroyed, absorbed in part, and a sclerotic mass is left. The dura, however, usually protects the cord from tuberculous infection and from suppuration, so that the cord process is not usually an inflammation. It is rather a tuberculous pachymeningitis with edema and more or less necrosis of the cord. If the tuberculosis can be arrested by fixing the spine or by surgical measures, the cord repairs itself; and as a result, in even very severe paraplegia from extradural tuberculosis, recovery may occur.

In most cases the compression disturbance seems to affect mostly the motor tracts leading to a spastic paraplegia with some pain, but no marked anesthesia. This is because, as shown in the following case, the lateral columns are especially sensitive to disturbance of nutrition, as is the case with syphilitic meningomyelitis.

In the following case, the necrosis edema, however, affected not only the lateral but the posterior column and central gray matter, leading to dissociation of sensation, such as is seen in syringomyelia and central hemorrhage of the cord.

The peculiar group of sensory symptoms, and the absence of kyphosis, make the case of rather unusual clinical type. The pathological findings show very clearly that the process in the cord lesion was a secondary one, due to the adjacent tuberculosis but not a part of it. The cord was not pressed out of shape, it had not reached a stage of softening, nor did it show any true inflammation change.

The term "compression myelitis" is a convenient one, but it does not indicate the true nature of the change, which should be called a pressure necrosis.

Summary.—Caries of fifth cervical vertebra complicating pulmonary and glandular tuberculosis; external tuberculous pachymeningitis; quadruplegia; dissociated anesthesia. Autopsy. Histological examination: Some necrosis edema; Gower's tracts traced to their decussation in the anterior medullary velum.

J. J., aged twenty-four years; married; negro; laborer; was admitted to the Second Medical Division of Bellevue Hospital, June 4, 1901. No family history bearing on the case could be obtained. Three years before had venereal ulcer of uncertain nature; no secondaries; no internal treatment. In 1899 contracted pneumonia, since then has had cough. On March 15 an exposure to cold was followed by severe pains in the arms, shoulders and back of neck. These pains continued and were very sharp. One month before admission a tumor had appeared in the left axilla.

Physical Examination on Admission.—Well nourished, muscular, slight general adenopathy. Rounded mass in left axilla, firm and painless. At the right apex anteriorly and posteriorly dulness on percussion with bronchial breathing and few moist râles. Temperature 103° F., pulse 84, respirations 20. Otherwise examination negative. Urine normal. Examination of sputum on June 14 and 15 for tubercle bacilli was negative. Leucocytes, 12,800.

June 27. The sharp, shooting pains in the neck and shoulders have continued with diminishing intensity. For several days he has complained of paresthesia in all four extremities with weakness. To-day on waking he found that he could not move his legs or arms. Since admission the temperature has ranged between 101° and 103° F. or 104° F., with a daily remission of from one to two degrees. Pulse and respiration in proportion.

June 29. The head is held slightly forward and fixed in one position. Movements of head such as flexion and rotation are carried out slowly and with difficulty. Lateral flexion is especially restricted and causes pain. A slight blow on the vertex induces severe pain referred to the lower cervical region. The lower cervical spines beginning with the fifth, are quite tender on percussion and also on deep pressure on either side of the spinous processes. This sensitiveness is particularly marked at the fifth cervical vertebra. The shock transmitted from a blow on the feet is felt acutely in the cervical region. No abnormalities in contour. Palpation of the pharynx negative. There is complete paraplegia with the exception of very slight movement of the foot and leg on the right side. The abdomen is distended, the muscles relaxed and powerless. The respirations are purely diaphragmatic. In the arms, movements of the shoulder-joint occur normally, but extension of the elbow-joint is quite lost on the right side and diminished on the left, while flexion is very weak, especially on the right. Extension and flexion of the wrist are so weak as to be scarcely perceptible and there is not a vestige of movement in the fingers. He has perfect control of bladder and rectum. Sexual power is undisturbed. The cranial nerves are normal. The arm-jerks are lost while the knee-jerks are very feeble, occurring only at every fourth or fifth trial. The Achilles-jerks are present on both sides; no ankle clonus; Babinski phenomenon on both sides. The upper and lower extremities are quite flaccid. The tactile and deep sensibility are well-preserved through-

out. There are analgesia and disturbance of the temperature sense extending as high as the second rib anteriorly and the midscapular region posteriorly. The abdominal and cremasteric reflexes are present.

July 6. The enlarged gland was removed from the left axilla and was pronounced, by Dr. Ewing, to be tuberculous.

July 23. Electrical: Strong Faradic currents applied to the paralyzed muscle groups of the arms produce no response, or only a very feeble, slow contraction. The muscles of the leg likewise do not respond to strong Faradic currents with the exception of the right adductor group. The muscles of the neck and face respond promptly. Very slight tactile disturbance (hyperesthesia) over the feet and legs. Pain and temperature senses are as noted above. The deep sensibility, except for slight uncertainty in the toes, is good. The knee-jerks are quite exaggerated; ankle clonus present on both sides; moderate spasticity. Still controls bladder and rectum. Sexual power retained.

Blood examination by Dr. Hastings. Red cells, 4,320,000; white cells, 11,800; hemoglobin, 85 per cent. Differential count. Polynuclear, 83⅓ per cent.; eosinophiles 1 per cent.; large mononuclears 7 per cent.; small mononuclears 8⅔ per cent.

September 19. Considerable edema of the lower extremities and face. Deep decubitus over sacrum. Breaking down of axillary tumor with formation of deep sinuses. The paralysis of motion and sensation and the reflexes remain as at

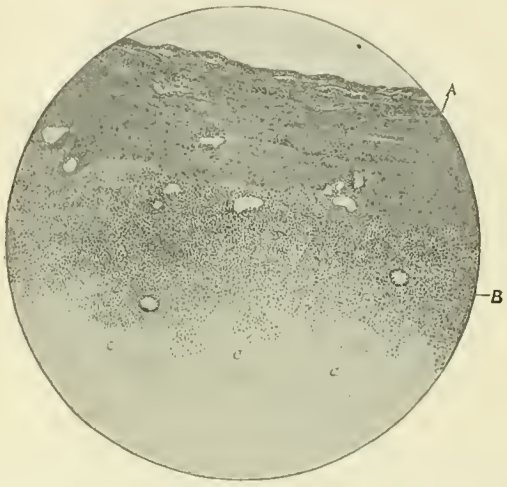
Fig. 1.

Section of fifth cervical segment at point of greatest extradural tuberculosis.

last examination. The sphincters of the bladder and rectum were continent up to the last. Died on September 25, 1901.

Autopsy was performed forty-eight hours after death by Dr. Otto Schultze. Large bedsores on the sacrum, both trochanters and the left scapula. The incision of the soft parts to remove the cord allows the escape of a considerable quantity of cheesy pus corresponding to the fifth, sixth and seventh cervical vertebræ. The muscles are infiltrated and necrotic. Deep sinus in the left axilla undermining and invading the pectorals. On removing the arches of the cervical column a large, cheesy mass was uncovered corresponding to the fifth and sixth cervical vertebræ and encircling the cord in its posterior aspect (Fig. 1).

Fig. 2.



Tuberculous peripachymeningitis. (A) Dura mater; (B) cellular proliferation outer surface of dura; (C) tuberculous mass.

This mass is entirely extradural. Tuberculous abscess formation in the left side of the neck bathing the trachea and esophagus in pus and laying bare the anterior surface of the cervical spine. The body of the fifth cervical vertebra is crumbled and broken down. Fistulous openings into the esophagus in the right side corresponding to caseating lymph glands. Extensive mediastinal and retroperitoneal glandular tuberculosis, large areas of tuberculous caseation and softening in both lungs; general miliary tuberculosis. Parenchymatous degeneration of the kidneys. Tuberculous ulcers in the small intestine. Sero-fibrinous pericarditis. An area of tuberculous caries on the inner aspect of the right frontal bone 3 cm. in diameter. Underlying this is an external tuberculous pachymeningitis. The brain, inner surface of dura and meninges are normal.

Histological Examination.—Transverse section at the site of compression, including the cord and peripachymeningitic exudate proved this to be entirely extradural. It consists largely of homogeneous areas of necrosis at the borders of which are dense accumulations of round cells including epithelioid and giant cells (Fig. 2). The blood vessels between the layers of the dura are thickened and surrounded by round cells. On the internal surface of the dura mater corresponding in extent to the peripachymeningitis, is a proliferation of endothelial cells. The adjacent endothelial cells of the arachnoid also participate. The walls of the anterior and posterior spinal arteries are normal; the lumen patulous.

The anterior roots are free. The posterior roots are the seat of extensive round cell infiltration and proliferation, compressing and obliterating the nerve elements. The gray and white matter of the cord contain numerous vacuoles and clefts, more numerous in the white than in the gray matter (Fig. 3). All the intramedullary

Fig. 3.

Tuberculous necrosis edema of cervical cord. Section shows an area of lateral column, the nerve fibers have almost entirely disappeared.

vessels are thickened and surrounded by round and spindle cells. The large multipolar cells of the anterior horns show marked changes; chromatolysis, peripheral dislocation of the nucleus, swelling of the nucleolus, hyaline degenerations, rounded and broken processes. Some few cells are normal. The anterior horn cells at other levels of the cord are normal. Above and below the site of lesion the usual secondary degenerations—ascending and descending—were followed by the Marchi method.

Remarks.—The interesting features of the case are as follows: The acute onset after exposure to cold; the three months' duration of the lancinating pains without other symptoms referable to the spine or nervous system, which, in view of the histological examination, were caused by infiltration and compression of the posterior roots; the very acute onset of the paralysis; the dissociated anesthesia with complete paralysis of motion which suggested the existence of a central lesion of the cord. The diminution of the knee-jerks at first followed by great exaggeration, spasticity and clonus, was probably caused by the shock of the acute onset.

The spinal cord nerve fibers showed swelling of myelin sheath and absent or swollen axis cylinders. Often the fiber is entirely gone, leaving only a vacuole (Fig. 3).

The dissociation of sensation is not explained by any distinct focus of central softening. The lesion of the cord substance seemed indeed most marked in the lateral columns and in the neighborhood of the posterior roots. This latter disturbance would not explain, however, the sensory disturbance in the lower limbs, and it must be inferred that the necrosis edema, by affecting partially the posterior columns and partly the ascending (Gower's) tract of the lateral columns, was the cause of this peculiar clinical symptom. The very distinct degeneration of Gower's tracts easily followed as far as the level of the corpora quadrigemina would tend to confirm the view that it is along these tracts that pain—temperature sense impulses are carried. No ascending degeneration was to be found in the inferior cerebellar peduncles, and no tracts were seen running in the formatio reticularis.

THE OUTLOOK FOR A MORE SANITARY STREET-CAR SERVICE IN NEW YORK.

BY GEORGE A. SOPER, PH.D.,

OF NEW YORK.

If it be true that the sentiment of the people is the supreme law, there is reason to take a hopeful view of the street-car situation in New York. The people who have long suffered in the densely crowded, unheated and unventilated cars of Manhattan have protested. Men have taken the time from business to stand on the street corners and count the cars and the people riding in them. It has been found that the crowding at midday, at night and on Sundays is approximately equal, and the reason for this has been discovered to be that the companies withdraw their cars as the number of travelers diminishes. The public has surmised that the refusal of the companies to issue transfers at certain points is animated less by a desire to prevent crowding than to increase the number of fares paid. It has been estimated that to run cars without sufficient heat represents a considerable saving in the electricity. To equip the cars with power brakes, to provide long cars with two conductors and to keep the cars clean and sanitary would mean considerable expense. This might be poor business policy for the companies.

Realizing that the interests of the companies are not entirely coincident with those of the public in the matter of comfort and convenience, when improvements which cost money are considered, the public has taken a deliberate stand for reform. The movement has no reference to the underground rapid transit road which is about to be opened. It is everywhere recognized that the carrying capacity of this line will not bring a sufficient relief to wholly remedy the existing conditions of overcrowding, and it will certainly not affect the policy of the surface roads so far as sanitary questions are concerned.

In a paper published in Medical News, April 19, 1902, I reviewed briefly some reasons for believing that the overcrowding of street cars, which was becoming more aggravated day by day in New York, was attended by grave dangers to health. Theoretical, as well as practical, reasons were given at the time to show that sanitation had been a neglected factor in the study of city

transportation, and that conditions existed in the cars of New York City which probably had something to do with the spread of respiratory diseases.

In the last two years health conditions have grown steadily worse. Crowding has increased and the cars have been less adequately heated and ventilated. The only visible improvement has been a slightly better control of the individual spitter. But even here the results are far from satisfactory. There are over thirty lines of horse cars on Manhattan Island, nearly all of which are in a disgracefully filthy, unheated and unventilated state. The condition of the elevated railroad is deplorable, particularly with respect to the stations. Not only are the waiting rooms, stairways and platforms inadequately cared for, but the plumbing connected with the closets, in many cases, greatly in need of repair.

But the odors and dirt of the stations, unpleasant as they are, are insignificant beside the sand-and-sputum messes on the platforms. Far from observing the sanitary ordinances, the public expectorates upon the floors and the company lays down sand for its accommodation. Later, the sand is scattered by the hurrying passengers and its dangerous elements, ground into dust, are scattered by the winds and draughts of passing trains. The sight of the slimy sand is nauseating to thousands who do not know its danger, while to those who understand what it means it is a matter of grave concern. No physician can doubt that the sputum-saturated sand contains the staphylococci and streptococci of suppuration, the bacilli of tuberculosis, the pneumonococci of Friedländer and other dangerous organisms. With respiratory diseases on the increase and pneumonia assuming practically the form of an epidemic, the suppression of this nuisance is a matter of the utmost public importance.

When such conditions are permitted to exist, it is time indeed that the indignation of right-minded people should be aroused.

The public movement for better street-car accommodations is little more than a year old and was the immediate outcome of conditions of overcrowding which had been rapidly approaching a climax. Credit for bringing the subject to a focus belongs to various associations of women, who publicly protested against the repulsive personal contact and frequent secret insult to which women passengers were subjected in the densely crowded cars. Following this initiative several organizations of professional and business men took the matter in hand, and through representations to the companies and by appeals to the authorities of the city and State, sought to alleviate the intolerable conditions.

Complying with a public demand, the State Railroad Commission held public hearings in New York and undertook an investigation of the conditions and their cause and cure.

The hearings partook somewhat of the nature of a suit, wherein the railroad companies were the defendants, and the public, through representatives of business men's organizations, tax payers' associations and health societies, acted as plaintiffs. To each charge of inadequate service the companies replied that the conditions complained of were indeed bad, but that everything was being done to remedy the situation which human skill and experience justified. The companies had the greatest, and practically the only, experts who were competent to pass judgment upon the alleged shortcomings of the companies, and these experts were working assiduously to improve matters. The whole question should be left in the hands of the companies, whose interest it was to carry as many passengers as possible.

The inquiry was not productive of the relief sought. The report of the railroad commission, where it did not wholly concur with the representations of the railway companies, advised changes which were either impracticable or productive of little benefit. With regard to sanitary reforms, the State Railroad Commission distinctly stated that this subject was outside of their jurisdiction. Improvements in the warming and ventilation of cars and in cleaning them, rested entirely with the New York City Department of Health.

Unable to obtain, by direct appeal to the companies or to the State Railroad Commission, the relief which it was believed could reasonably be afforded, organizations of business men, one of which is known as the Merchants' Association of New York, undertook to secure reforms by carrying the subject to the legislature.

Preliminary to the introduction of a bill at Albany, however, the Merchants' Association undertook to gain a better knowledge of the transportation question as it related to improving the surface and elevated railroad services of Manhattan. A committee was formed, with a subdivision on law and one on engineering and sanitation.

The committee on engineering and sanitation was composed of five members, all of whom had had considerable experience in transportation or sanitary problems.

It was realized by the committee at the outset that the problem faced by the railway companies was one of unprecedented scope. Nowhere else had such a vast number of passengers to be accommodated on lines within so small a territory. From computations made from data supplied by a report of the Board of Railroad Commissioners of the State of New York, it was found that about 1,000,000,000 passengers are carried yearly by the surface and elevated lines of Greater New York, which is about one-fifth of the total street railway transportation of the whole United States. The amount of travel per inhabitant has increased greatly within recent years. It is said that in 1853 each inhabitant of New York city used the public conveyances on an average of 13 times a year, while each inhabitant of Manhattan Island now uses the elevated and surface roads on an average of 415 times a year, or 32 times as often.

In studying the transportation problem of New York, the committee on engineering and sanitation undertook to examine into a series of specific questions, and believing that a solution of the most difficult would make the others comparatively easy, the committee directed its attention principally to Manhattan Island. A corps of trained observers and a staff of office assistants were engaged to collect and collate data on the various points under consideration. Many months were spent by the committee in their investigation in New York city, and visits were made to Philadelphia and Boston to observe transit conditions. The formal report of the committee to the Merchants' Association has recently been printed and issued in book form.

The technical work of this committee has shown: That more cars can be put in operation on the surface lines at all hours of the day and night; that the overcrowding which is customary at other than rush hours is caused by the withdrawal of too many cars from the lines; that it lies within the power of the companies to largely increase the car service on all but the most congested streets; that the carrying capacity of the Broadway line could be increased more than 70 per cent. by the substitution of cars having a seating capacity of fifty-two, instead of the average seating capacity of thirty passengers of the closed cars now used; that to guard against accidents power brakes should be substituted for the hand brakes now employed; that the safety of passengers demands that two employees beside the conductor be placed on all cars having a body length of twenty-eight feet or more; that many of the stations of the elevated road are inadequate and out of repair, and should be provided with wider stairs, covered platforms and arrangements for separating the streams of incoming and outgoing passengers.

Among the principal sanitary conclusions arrived at by the committee, the following may be mentioned:

Among the insanitary conditions prevalent are the sand piles used in lieu of spittoons on the elevated railroads. It is impossible to conceive of a greater menace to the public health than these. The sand which is thrown upon the platforms invites and receives infectious material from the lungs and throats of sick persons to an extent which is as dangerous to health as it is disgusting to sight. The expectorated material becomes dried in the sand and is distributed by winds and by travel of passengers through the cars and stations and through the atmosphere of the street below. The sand pile nuisance is the most insanitary condition which calls for attention in connection with the transportation problem in New York City.

A provision of the Sanitary Code requires that the elevated railroad company should provide cuspidors for use on the elevated platforms. The number is now insufficient, and those which are in use are too small. It is desirable that cuspidors of ample size and decent appearance should be provided. Observation shows that where these conveniences are properly supplied they are generally used by the public.

If the spitting ordinance cannot be construed so as to prevent passengers and elevated train men from expectorating into the streets and onto the tracks, it would be desirable to so modify it that this objectionable practice may be forbidden.

Better care of the stations is needed. At present proper attention is lacking in this respect, and the waiting-rooms, closets and platforms are not uniformly maintained in a cleanly or orderly condition. Dirty pails should not be left standing in the waiting-rooms or passageways; dust and dirt from the platforms and stairs should not be swept into the streets. It should be a rule that no dust is to be raised in cleaning. The methods of cleaning which are suitable for the stations, including platforms and stairways, require the use of mops, soft hand brooms and cloths. Stiff brooms should not be used. Sand should never be used anywhere on the station floors, platforms or stairways, unless to guard against slipperiness.

It is recommended that the cars be cleaned more thoroughly. More attention should be given to systematizing this matter, so as to avoid such objectionable practises as the morning running of cars which have been used all night.

The use of cocoa mats on the floors of cars has frequently been condemned. They serve as collecting and propagating places for bacteria, and it is impossible to clean them. Attempts to disinfect such articles, except in large and expensive sterilizers, are useless.

Other objectionable floor coverings include slats or strips of wood permanently fixed to the floor and which cannot be cleaned without the raising of dust, which is objectionable. The floors of the cars should be covered with a smooth, nonporous material, or a grating of non-absorbent material which may be easily removed for cleaning.

The catch-pans, which are located under the tracks to catch drippings, should be regularly and systematically inspected and kept clean. Under the present circumstances, the catch-pans serve not only to collect drippings, but also as reservoirs of filth.

At present the toilet-rooms of the stations are not always clean. In many cases the plumbing is out of order, the closets overflowing and the waste-pipes stopped. It is unnecessary to point out the objectionable nature of these insanitary conditions.

Proper attention to the ventilation of the stations is needed. Better ventilation may be secured by the careful regulation of transoms, windows and ventilating devices, whereby the air may be continually refreshed and unpleasant odors avoided.

The stations should be warmed in winter to a temperature between 55° and 65° F.

It is desirable that the cars of the elevated railroad should be improved with respect to venti-

lation and warming. An advantageous way for improving the air of the cars without drafts is to provide for the introduction of air at a greater number of points. The ventilation is more satisfactory on the elevated roads than on the surface cars, but it is by no means all that could be desired. More air should be admitted and a part of the air should be carried over the heaters, for the double purpose of warming the fresh air and reducing the intensity and concentration of the heat now given off under the seats. There are various means of accomplishing this end. The experiments of the Pennsylvania Railroad Company and a popular device now being employed on the windows of large office buildings furnish excellent illustrations of the practicability of this method.

The temperature of the cars should be more carefully regulated and placed under the control of the conductor of the train, who is best able to judge of the need of adjusting the warming and ventilating apparatus, and he should be properly instructed and held responsible. Under the present circumstances the cars are allowed to become sometimes too warm and frequently too cold. The temperature should not be permitted to fall below 55° F. nor in cold weather to rise above 65° F.

In order to improve the ventilation of the cars of the surface roads, the same recommendation is made which was offered in connection with the cars of the elevated road. The air should be introduced at a greater number of points, and some of it should be permitted to pass over the electric heaters under the seats. Under the present conditions there is not enough fresh air in the cars; there is no systematic ventilation; the employees of the road do not appear to be instructed to follow any rules with respect to ventilation; the temperature is not maintained within proper limits. The committee believes that while there are difficulties in the way of securing satisfactory ventilation, and that perfect results cannot be secured when cars are overcrowded, a very considerable improvement could be secured by systematizing the ventilation and warming. As an aid to ventilation, it is recommended that the transoms in the monitor tops be protected on the outside by guards to prevent the entrance of sudden gusts of wind. The transoms should also be connected and operated by a lever placed at the ends of the car and controlled by the conductor.

The spaces under the seats of horse cars, where now closed, should be opened, so that the dirt and refuse often thrown into the window casings behind the seats may be seen and promptly removed.

The floors and seat coverings of cars should be kept clean. Many of the surface cars at present have fixed slats on the floors and some have cocoa mats.

Wherever the public is subjected to exposure while waiting to take cars at termini or when transferring from one car line to another on the surface roads, suitable shelter should be provided. If physical conditions at those points are such that shelter cannot be provided in close proximity to the tracks, it should be provided in nearby buildings.

The interest shown by the Merchants' Association by no means represents the total effort being made by the people of New York city for improved conditions of transportation. Other organizations, notably the West Side Association, the Taxpayers' Association, the City Club, and some other forces, are at work to bring about improvements which the public feels it has a right to demand of the companies.

So far, the public movement for better street-car accommodations has been characterized by moderation and energy on the part of the people's representatives. The whole public is unanimous in demanding better facilities than can be afforded by any improvements now in sight. Each organization believes that important reforms can be obtained if a firm stand is taken toward the companies, and each is apparently ambitious to be the successful champion of the popular cause. A combination of the various forces at work might be desirable, to make the whole movement more effective, but so far as is known, no attempt at a combination of the various efforts has been made.

THE EARLY DIAGNOSIS OF GENERAL PARESIS.*

BY WILLIAM A. WHITE, M.D.,

OF WASHINGTON, D. C.;

SUPERINTENDENT GOVERNMENT HOSPITAL FOR THE INSANE, WASHINGTON, D. C.; PROFESSOR OF NERVOUS AND MENTAL DISEASES, SCHOOL OF MEDICINE, GEORGETOWN UNIVERSITY, WASHINGTON, D. C.; PROFESSOR AND CLINICAL PROFESSOR OF MENTAL DISEASES, MEDICAL DEPARTMENT, COLUMBIAN UNIVERSITY, WASHINGTON, D. C.

I HAVE been prompted to choose this subject of the "Early Diagnosis of General Paresis" for my paper on this occasion by a number of experiences I have had in the past few months. Experiences, while they may not be uncommon for one who sees a number of cases of paresis each year, still are not so generally known but that they will bear comment.

Protean as are the manifestations of this disease it is not strange that it should often go unrecognized during its early stages yet there is probably no disease in which a failure to make a correct diagnosis is fraught with such manifest dangers not only to the patient but to his family, his friends, or in fact to any one who, not recognizing his condition, may be induced, for instance, to enter into business relations with him. It is during this early period that those unfortunate occurrences are so frequent which might have been prevented if the true condition of the patient had been recognized.

Manifesting itself in its incipiency by symptoms of defective intelligence, lack of judgment, memory defects, and moral obtuseness we frequently see the most pitiful of pictures—a pre-

* Read before the Broome County Medical Society, Binghamton, N. Y.

viously respected citizen, father of a family who occupy an enviable social position become at the height of his career an ardent worshiper at the shrines of Venus and Bacchus. Friends and relatives see nothing in these manifestations but the outcropping of original sin and are distracted by their inability to stay the career of drunkenness and vice upon which their erstwhile respected relative has apparently entered. How many heart aches, how many pangs of anguish, how many blushes of shame could be spared the wife and children of such a man if the family physician did but recognize in these occurrences the symptoms of the onset of a mental disease and could advise them what course to pursue?

An acute attack of maniacal excitement, the delirium of an acute toxic psychosis, are early recognized and even the slowly developing depression of the melancholic, or the gradual change of character of the paranoiac is usually appreciated before any serious harm can come. But here we have a disease, afflicting one when at the very zenith of his physical and mental powers, insidious in its onset yet capable of so changing the character in a few weeks that the previously honest, upright, moral, truth loving, sober citizen becomes the votary of every form of vice, sinks to the depths of drunkenness and debauchery and may even stain his hands in blood. But this is not the worst, all these things would ultimately find their explanation when the disease that was responsible for them came finally to be recognized and in the light of its diagnosis they would be excused. But it so happens that such a man as I have pictured to you is generally the guardian of the family exchequer. When this is the case it almost invariably happens that he wastes considerable amounts of money in his debauchery, becomes involved in unfortunate and ill-advised speculations often at the solicitation of "sharpers" who only too well appreciate his poor judgment and gullibility—and finally, when he was succeeded in hopelessly entangling his business affairs and plunging himself into debt he is committed to an institution and his family only then come to a realization that they are penniless. The pity of it all is that it might have been prevented.

It is because I have had the possibilities just outlined impressed upon me by a number of cases of late that I thought of taking up with you this evening a discussion of the diagnosis of paresis and the signs and symptoms on which such diagnosis depends.

Before starting on a detailed discussion of the separate factors on which a diagnosis of paresis rests I wish to call your attention to the pretty generally diffused misapprehensions regarding it. First, the diagnosis of paresis does not rest primarily upon the mental symptoms. Paresis is a gross organic disease of the brain and its diagnosis must rest in the main upon an appreciation of the physical signs which these changes bring about, particularly in the field of motor disturbances. Second, grandiose delusions of great wealth, power, and strength are in no wise a necessary part of the disease and while the so-called classical type of paresis does present such delusions, still there are excellent reasons for believing that this type is becoming less frequent.

Now to begin with, let us consider first, for convenience, the least important features of paresis for diagnostic purposes, namely the mental symptoms. I have already indicated in a general way what these are. They are symptoms of dementia, gradual, progressive, and uniform failure of the mental powers upon which, it is true, may be engrafted the picture of almost any psychosis but which inevitably and of necessity modify that picture in a way more or less characteristic of the underlying defect. This dementia manifests itself by failure of memory, defective judgment, inability to apply the mind consecutively for any length of time, and failure of the moral sense. The picture from a mental viewpoint is then one of a gradually deepening dementia, correlated with organic changes in the cerebral cortex—to my mind a true organic dementia. If upon this basis of organic dementia there be erected mayhap symptoms of excitement or depression, delusions of a hypochondrial or grandiose nature, multiform hallucinations and illusions, a true delirium, these symptoms may properly be considered as unessential, accidental accompaniments. Developing as they do, however, upon a ground work of dementia we would expect them to manifest themselves differently than would be the case if their foundation had been originally an unimpaired mind. This we find preeminently to be the case. The grandiose paretic is not content with possessing a few paltry thousands but reckons his fortune by quintillions, he has solid gold carriages, harnesses set in precious stones and offers me each morning a fleet of ships to go around the world with, a million dollars and a thousand wives. The depressed paretic has caused the deaths of untold myriads of human beings, the hypochondriacal has no stomach, no bowels, no brains, etc. The delusions are marked by an absurdity which can only result from the defective judgment, and impaired intelligence of dementia.

These advanced conditions of delusional states, however, are not what I desire to particularly call your attention to, I merely wished to illustrate fully what I meant by my statement that the dementia of paresis was the underlying and essential mental symptoms. The demented type, without marked delusions or sensory falsifications is the truly typical variety of the disease and the dementia the basal element of all forms. This dementia may, however, not be apparent, it may be necessary to seek for its manifestations. In the very early stages the outward symptoms may be those of irritability, and an untoward restlessness which may exhibit itself in many ways, as for instance useless business activity, fits of violent rage over trivial annoyances, and slight lapses of memory. If the reasons for all these things be inquired into, however, they will be found inadequate, often puerile.

Let us turn our attention now to the more characteristic physical signs of the disease which may be found in its earliest stages. Of these by far the most important are the oculo-motor and tendon reflex disturbances.

Of the oculo-motor phenomena the pupillary abnormalities are most important. The loss of the light reflex with retention of the reaction to accommodation, the Argyll-Robertson pupil, is one of the most valuable diagnostic signs of beginning paresis, in the absence of tabes, as it frequently occurs very early. Siemerling* in an examination of 9,160 insane persons found this symptom in 1,639 and of this number 1,524 were paretics. A sluggish reaction to light is also sometimes found, a condition which probably is the beginning stage of the Argyll-Robertson pupil. In examining for these conditions care should be taken that movements of accommodation are not mistaken for reactions to light by having the patient fix the gaze upon some object, the pupils should be equally illuminated, and the light should be not too bright, as under these circumstances a sluggish reaction might be masked. Earlier still, Berkley believes, can often be found loss of the consensual light reflex. The consensual reflex consists in the dilatation and contraction of the pupil of one eye when the other is shaded or exposed to direct light. It is quite possible, I believe, that the loss of this reflex is also an earlier stage in the development of the Argyll-Robertson pupil and should always be tested for. This condition is usually found when a sluggish light reflex is present. Lewis† claims that a still earlier symptom than any of these is the loss of the sympathetic reflex (the dilatation of the pupil on stimulating the skin of the neck). 63.6 per cent. of his cases showed this symptom, several of them with normal light reflex both directly and consensually.

Of the tendon reflexes the only one that need be considered is the knee-joint. This may be normal, exaggerated, diminished, or lost on one or both sides. The exaggerated reflex is most common, but I agree with Sommer‡ in his statement that although this is so the absence of the knee-jerk is of much greater diagnostic importance as there are many more causes for its exaggeration other than paresis than there are for its abolition. This sign also, of course, depends for its importance upon the elimination of other possible etiological factors, especially tabes.

If now we find a patient in middle life with Argyll-Robertson pupils and abolished knee-jerks and tabes can be eliminated, we may strongly suspect paresis. If in addition we learn that there has been a great change of character in the individual, if he has become irritable and restless, fails to remember business engagements, is less careful of his personal appearance, and presents, in short, a host of minor mental symptoms which individually mean nothing but in their ensemble speak for mental deterioration, we need not hesitate to be convinced.

It is rare, however, that a diagnosis has to be made from such meager facts. Other signs are usually available. First of these I would call your attention to the speech. The stammering, stumbling, hesitating speech of the advanced case with its syllabic reduplications and omissions and often explosive character is something so characteristic that once heard it is never to be forgotten. But when there exists this amount of trouble the diagnosis is easy. It is in the very early stages that the special defects are often difficult to make out. At this time there may be only a suspicion of the true paretic speech in the slight hesitation and occasional almost unnoticeable defect in a single word. Such patients often say test words such as, hippopotamus, communicability, circumstantiality, perambulator, quite correctly. It would seem that the defect is as yet so slight that the mere effort expended as the result of conscious attention is sufficient to overcome it. In such cases the test words should be combined into sentences to catch the patient unawares as it were. I have a patient now who says test words and phrases perfectly, yet there is a noticeable defect in an occasional word in her ordinary conversation. If she be asked, however, to repeat this word it is done promptly and correctly. If the speech defect is slightly more marked we may notice a slight tremor about the muscles of the mouth which is brought out by a difficult word or by emotional excitement. We should be careful in interpreting this tremor, however, as we find it present in many conditions other than paresis.

Characteristic of paresis, and occasionally but not frequently occurring early in its course, are the so-called paretic seizures. These may vary in severity and character all the way from the light syncopal attacks with pallor and temporary prostration to severe apoplectiform and epileptiform crises. The epileptiform attacks may be of the petit mal or grand mal type and without the history are indistinguishable from true epilepsy. The apoplectiform seizures resemble in every way true apoplexy but the resulting paralysis is less apt to be permanent, in fact it may entirely disappear in a most remarkable fashion in two or three days. Transitory muscular paralyses, not infrequently of the extrinsic eye muscles may, however, occur apart from these seizures. They usually are of short duration and clear up rapidly.

These then are the symptoms we must look for as early manifestations of paresis: Argyll-Robertson pupil, abolished knee-joint, slight speech defect, transient palsies, and paretic seizures accompanied by a gradually progressive mental enfeeblement. The only other early symptom that is diagnostically of importance is optic nerve atrophy but although this is often of early onset it is from its very nature usually overlooked. I have in mind now a case, however, who spent much time during the early stages of his disease in endeavoring to get his vision corrected and

* Cited by Berkley in "A Treatise on Mental Diseases."
† W. Bevans Lewis: "A Text-book of Mental Diseases."
‡ Robert Sommer: "Diagnostik der Geisteskrankheiten."

whose condition was apparently not recognized by any of the men he consulted regarding his eyes.

As a rule our patients come to us with much more marked disturbances than I have outlined. They generally present well-marked speech disturbance, a similar defect in writing marked by tremor, omission and reduplication of syllables and words even to complete illegibility, tremor especially of the facial muscles, muscular weakness, transient or permanent palsies, and maybe a history of seizures, together with a well-marked dementia or possibly the symptoms of a well-developed psychosis. These further symptoms I shall not discuss as the early ones are still all present and the diagnosis is usually easy.

The principal diseases for which paresis may be mistaken in these early stages are tabes, acquired neurasthenia, some one of the pure psychoses, alcoholism, brain tumor, cerebral syphilis and disseminated sclerosis.

The principles of its differentiation from the various psychoses I have indicated already. The presence of the underlying dementia in a person of middle age should make us at once suspicious and if to this condition the physical signs can be added a diagnosis can with certainty be made.

From tabes dorsalis the differentiation is not so easy and in fact there remain a few cases where it is impossible and we must wait for the development of further symptoms. This is due to the fact that in their early stages the physical signs may be identical in the two diseases. When, however, we observe a case in which the tabetic signs are somewhat atypical with for instance preservation of knee-jerks or marked ataxia of the arms we may be suspicious of paresis and if with this condition we find associated evidences of dementia a tentative diagnosis is in order.

In differentiating paresis from acquired neurasthenia the general mental attitude of the patient is of great significance. Whereas the neurasthenic is given to exaggerating his ills, to constantly complaining of his aches and pains and keeps close observation of every change of symptoms, the paretic is usually indifferent or may on the contrary consult a physician under protest and in the firm belief of the uselessness of so doing as he feels so well. This is not invariable, as I have seen paretics well advanced in the disease who were much concerned over their condition. The contrary state of mind, as illustrated by one of my parents, is more common. On her admission I discovered a well-marked left hemiplegia which she actually knew nothing of until I called her attention to it. In addition to this there is in neurasthenia no dementia, no disturbance of speech or writing, no history of seizures, the tendon reflexes are equal and not abolished, the pupils equal, respond to light and accommodation and are more apt to be dilated while in paresis they are frequently unequal and often very much contracted.

From alcoholism the diagnosis is often not so easy. The deterioration of the chronic alcoholic has much in common with the dementia of paresis. Here again we must turn to the physical signs and note carefully the historical facts. Following a long debauch, however, symptoms may arise, which, in the absence of a history, would warrant a diagnosis of paresis—the so-called alcoholic psuedo-paresis. These symptoms disappear, though in a remarkable manner when the alcohol is withdrawn.

Symptoms occasionally develop in the course of brain tumor which closely resemble paresis. The diagnosis must be made on the preeminently focal character of the physical signs in the former disease.

From disseminated sclerosis the differentiation is sometimes difficult. The combination of intention tremor, nystagmus, scanning speech and spasticity will, however, usually leave little room for doubt although some of these cases do ultimately develop the typical signs of paresis.

From cerebral or cerebrospinal syphilis the diagnosis is again quite difficult. If the lesion is a gummatous meningitis the signs are rather of multiple lesions than a diffuse process. If, on the other hand, the disease affects principally the vessels with resulting endarteritis obliterans, thrombosis and softening, the symptoms are focal and convulsions developing afterward constitute a true post-apoplectic epilepsy. Disturbances of speech and writing either are not present or, if they are, do not partake of the nature of a paretic disorder but are true aphasias due to focal lesions. Palsies, if present, are permanent and nocturnal headaches common. Antisyphilitic remedies produce immediate results in many cases.

In discussing the points of differential diagnosis I have not aimed to be exhaustive but rather succint. I have merely taken up the various factors which one should know to make an intelligent diagnosis and only those which the practitioner will find practical and such as are apt to be met with from day to day rather than the unusual and rare. Even if a certain diagnosis in a given case is impossible the presence in more or less degree of one or more of the symptoms outlined may serve to put us on our guard and by a solicitous watchfulness prevent those unfortunate occurrences often the result when the disease goes unrecognized for any length of time.

PULMONARY TUBERCULOSIS AS AN INFECTIOUS DISEASE; ITS EARLY DIAGNOSIS.*

BY JAMES J. WALSH, PH.D., M.D.,
OF NEW YORK;
LECTURER ON GENERAL MEDICINE AT THE NEW YORK POLYCLINIC AND SCHOOL FOR GRADUATES IN MEDICINE.

It is over 100 years now since it began to be suspected that tuberculosis was probably an infectious disease. It is nearly forty years since Villemin proved its infectious nature. For the last twenty-five years its contagiousness has entered as a precious bit of popular hygiene and

* Read at the annual meeting of the New York State Medical Association.

sanitary science into ordinary tradition. All this has been with the happiest results, and to none have they been more welcome than to physicians, yet the members of the medical profession have not yet practically applied the recently acquired knowledge of the disease as one of the group of contagious diseases. With regard to the other diseases of this group, the physician's first question, when called to see a case and when he suspects an infectious disease is, "Have you been exposed to any contagion? Are there cases of contagious disease in the neighborhood?" The most helpful auxiliary in diagnosis is the knowledge that there are other cases of the same kind with which the patient has been in contact.

Since then tuberculosis is a contagious disease this should be the first care of the physician to ascertain whether the patient has been in contact with others suffering from the disease either at home or at school, or at work. Should contagion prove to have been possible, even if there are no definite localizing symptoms of the presence of a contagious disease, the physician takes the pulse and temperature and if these are at all disturbed he does not consider that he is justified in making a negative diagnosis, even though he finds no local symptoms confirmatory of his suspicions. The patient is warned of the possibility of there being an infectious condition present and is asked to take proper precautions as regards rest, diet and due care until there are no further disturbances of pulse or temperature to be found.

It seems to me that these three preliminary subjects, contagion, the pulse and temperature, which appear to demand so much attention in other infectious diseases, should have the same prominence given them in the physician's mind in cases where tuberculosis is suspected.

At the present time we realize better than ever before the necessity for the very early diagnosis of tuberculosis. Incipient cases may be perfectly cured. Initial cases, where the lesions have not become destructive, may be relieved to such an extent and a curative reaction promoted to such a degree that the diseased area may become completely walled off and, with proper precautions, never again give any trouble.

With regard to the first of these, the possibility of contagion, not near enough attention is usually given. As a rule, the patient is asked whether other members of the family are suffering or have suffered from the disease. This seems to countenance the old idea of the heredity of tuberculosis, and the patient's replies are usually framed on this hypothesis with consequent loss of information that might be of service to the physician in many cases. The important question is not whether relatives are suffering from tuberculosis, but whether any of those living in the same house are apparently suffering from the disease. It is not alone the living rooms, however, that are important in this matter, but especially the workrooms. Those employed in factories should be asked whether any of their coworkers are suffering from chronic cough or whether any of those with whom they associate frequently have such an affliction.

In this respect the occupation itself is often of importance. It is well known for instance that laundresses, that is to say, washerwomen, suffer nearly twice as frequently as other working women of the same class in life from tuberculosis, because of the facility with which they contract tuberculosis from infected clothes. Another class of working women, who suffer severely in the same way are scrubwomen, the contagion evidently being attributable to the careless habit of expectoration that still obtains, notwithstanding the crusade in this matter in recent years.

With regard to the other two preliminary matters for observation, the pulse and temperature, it has seemed to many observers that the solution of much of the mystery of very early cases of tuberculosis is contained in them. As soon as a chronic infection develops anywhere in the body there is a disturbance of the pulse. Especially when this infection is due to the tubercle bacillus, the pulse may be disturbed a long while before any sensible variation of temperature is caused by the toxins of the bacteria. It is well known that cold abscesses may not produce any variations of temperature, and yet may be detected by the fact that the patient's pulse rate is usually far from normal and subject to facile and frequent variations for very slight causes.

When a patient comes for diagnosis, in whom there is suspicion of tuberculosis and the pulse is found to run above 90, even when there is no excitement it is more than probable that there is something wrong somewhere in the body. It is well to remember in this respect that insurance companies refuse to take risks on subjects whose pulse is not below ninety at the time of the medical examination. Of course, a single examination may mean nothing in this matter. The only way to obtain definite information is to have the patient keep a daily record of the pulse movement, that is to take the pulse regularly three times a day and after four or five days present the record to his physician.

A rapid pulse tells the tale of a chronic infection in the body sooner than anything else and the presence of a pulse constantly above 85, running above 90 in the afternoons, is of itself a very suspicious circumstance, unless of course it occurs in persons who are known to have a family tendency to rapid pulse. The toxins of the tubercle bacillus absorbed into the system disturb the pulse usually a good while before they cause any disturbance of the temperature. In fact, there are those who insist that there is never any disturbance of the temperature until secondary infection of tuberculous foci has taken place and consequently pyogenic toxins are being absorbed into the system.

With regard to the temperature, however, it is important not to depend on one or two or even three or four observations, especially if those ob-

servations are taken about the same time of day. There is, as is well known, a physiological rhythm of temperature, in every individual, with a difference between the lowest and highest daily temperature of at least a degree and a half, Fahrenheit. While the average daily temperature is about 98.4° F., the morning temperature, that is before eight o'clock, is often 97.5° F., or even lower. The afternoon temperature may be as high as 99° F. No two individuals are exactly in accord in this matter. The variation between lowest and highest should be, however, less than a degree and a half. If an individual presents a daily temperature range of more than a degree and a half, there is probably some fever present. If the variation is more than two degrees it is practically sure that there is a febrile movement in the case.

As was pointed out by a German observer, Dr. Marx, in Professor Brieger's clinic, at the Charite in Berlin, the morning temperature in healthy individuals is not infrequently below 97° F., and consequently the afternoon temperature should not exceed 98.5° F. to be within the normal. There is only one way to decide whether the patient's temperature is abnormal and that is to have a series of observations extending over a number of days, at least three to five. The temperature should be taken before eight in the morning, shortly after noon and about six in the evening. If the daily temperature range proves to be more than a degree and a half then there is ample confirmation for any suspicions that may have been aroused with regard to the presence of tuberculosis in the case. At least, it is sure that there is some factor disturbing the bodily heat regulation and consequently leading to perhaps serious metabolic derangement.

These may seem refinements of diagnosis. No patient who is suffering from the hideous thought that perhaps incipient tuberculosis is already at its ravages will find the request for pulse and temperature observations extending over several days too inconvenient. On the contrary, they will usually appreciate the definite information that is thus afforded their physician with regard to their bodily condition and will not hesitate to be of all the assistance possible in so important a matter.

To have discovered that the pulse and temperature are disturbed and even that the patient has been exposed to tuberculosis, does not definitely settle the diagnosis of pulmonary consumption, but it gives the physician important auxiliary information. Especially are these circumstances strongly corroborative of any suspicions of disease that may exist for other reasons. If the patient has been bothered by a cough that has persisted for some time and has been accompanied by some loss of weight, then there can be very little doubt of the nature of the disease. Knowing the patient's general condition in this way, the preliminary knowledge for a proper appreciation of even very slight physical signs in the lungs is secured.

In older days, physical diagnosis laid much stress on the recognition of cavities in the lungs and of even the size and shape of cavities. Gerhardt's change of note, caused by the diameter of the cavity being greater in the horizontal or the vertical plane with a consequent difference in the form of the cavity if it contains any secretion when the patient's position is changed, was one refinement. Wintrich's change of note, due to the emptying of a cavity containing secretion, was another. Stress is laid on various physical diagnostic signs, which were supposed to differentiate various degrees of degeneration in the lung. Practically all of these rather difficult refinements of physical diagnosis are useless as far as any good to the patient is concerned. If the disease has advanced to the stage of cavity formation, then very little information of any significance as regards treatment or even prognosis can be gathered from even the most careful refinements of physical diagnosis. The progress of the disease depends not on its extent but the individual resistive vitality.

The important consideration is to discover the disease at the earliest possible moment and by warning the patient of its ravages secure his complete cooperation for its cure. Diet and fresh air will, at an early stage of tuberculosis bring about a complete cure of the disease. To wait, however, until percussion will give the definite information in this matter, or until bacilli are discovered in the sputum, is frequently to delay the assurance of diagnosis and consequently put off the careful treatment needed for these cases.

By percussion, as was shown by Oestreich working in Virchow's laboratory, no lesion smaller than a large cherry can be detected. Even for this the lesion must be situated rather close to the surface of the lung. Tubercle bacilli frequently do not appear in the sputum until after extensive consolidation has taken place.

As a matter of fact not rarely tubercle bacilli do not appear in the sputum until there has been a secondary infection of the affected area through the wall of the bronchus. Unless the tuberculous focus is close to the bronchus there may be considerable consolidation before any true tuberculous material finds its way into the bronchial lumen to be expectorated. If possible, the diagnosis must be made before this time. Almost as soon as any consolidation takes place, however, there is a roughening and a lengthening of the expiration in the affected area. This is the first physical sign that can be detected. Alone it is scarcely enough to make the diagnosis of tuberculosis absolute. If there is disturbance of pulse and temperature, however, together with a localized area of prolonged, slightly roughened expiration, then there can be no reasonable doubt of the existence of the tuberculous lesion. There is no need to wait for râles and the crepitant râle which is sometimes depended on as one of the earliest auscultatory symptoms of tuberculosis is not heard in those cases until the tuberculous process has affected the pleura and thus caused

the adventitious sound which is recognized as a râle.

The first part of the lung to be affected is the posterior portion of the apex, as a rule. The left apex is said to be a little bit more frequently affected than the right apex, and the statistics of cured cases of tuberculosis, as seen in the post-mortem room, seem to bear this statement out, but this greater frequency of liability to invasion by tubercle bacilli is not sufficient to make it of the diagnostic importance it sometimes is considered. It is not always the custom to examine the posterior portion of the upper part of the lung. Examinations are made just below, and occasionally above, the clavicle in front, while the more important posterior portion is neglected. When there is no sign beneath the clavicle, differences in the breath sounds are often noted above in the superscapular region.

This portion of the thorax, then, should always be examined with the greatest care. Any difference in the breath sounds is very significant. Another portion of the lung, only affected in anomalous cases, though these occur with sufficient frequency to make it of some importance, is along the lower border of the upper lobe. In order to detect physical signs the examination must be made just above the line connecting the nipples. Too much insistence, however, cannot be placed on the teaching that even the earliest physical signs in tuberculosis cannot be said to represent an incipient stage of the affection, but rather one that is already considerably advanced.

What I would plead for, then, in cases of tuberculosis, is the detailed study of the individual, taking account of all the constitutional symptoms, of the environment of the patient as regards possible tuberculous contagion, so as to recognize the earliest disturbance caused by the presence and growth of the bacillus in the tissues. If cases are detected before physical signs are present to confirm the diagnosis there will always be a doubt as to whether the case was really tuberculous or not; but provided patients get better, improve in general health and survive the danger of tuberculosis, there will be no justifiable criticism of prematurity of diagnosis. Early cases of tuberculosis are comparatively easy to cure; late cases are impossible to cure. The earliest possible detection must be the watch-word of the progressive physician.

PATHOLOGICAL CHANGES IN TISSUE UNDER THE INFLUENCES OF THE X-RAY. *

BY WILLIAM S. NEWCOMET, M.D.,
OF PHILADELPHIA.

The subject of the pathological change in tissue under the influence of the X-ray is one of considerable latitude, and in this article it will be covered only in a general way, as detail must be avoided on account of time. In dealing with this subject in another paper, it was considered under two heads: first, the change observed in normal tissue; second, in abnormal tissue; and the conclusions reached at that time seem to still hold good. That no single form of degeneration alone is characteristic to the X-ray, and the form of degeneration observed depends entirely upon the tissue exposed and the method of X-ray application. Here may be seen the scope of this study and the cause of the great difference of opinion that exists among various authors. In some ways the effects of the X-ray might be compared to fever, as for instance in a case of high fever the first degeneration that usually takes place is a hylogranular, then, if the temperature continues, a fatty change follows, the recovery here depends upon the amount of damage done before the fever subsides. In another case, where the fever is continued for a long time with remission and intermission, we have the more chronic forms of degeneration, such as the amyloid change, etc. The X-ray is capable of the same latitude. Those who have watched an X-ray tube in operation and noticed how the vacuum will change from time to time will wonder how any constant result can be obtained, but the operator after a little practice will be able to judge to a great extent about how much energy a certain lamp is capable of giving under certain circumstances.

Then again, with this wide variance of X-ray energy, we have a still more important irregularity to consider, and that is the tolerance of the X-ray by certain individuals always being on guard for that person who has a frightful susceptibility to unpleasant effects. And what seems still more extraordinary is the fact that a person will tolerate a certain amount of X-ray from one apparatus, while apparently the same amount from another will cause trouble. No doubt this is due to our imperfect methods of measuring the amount of X-ray energy. Some have thought that the so-called "brush effects" have a great deal to do with these unexpected results, but if this is so it seems queer that we have not seen these changes before in other fields, but this subject still needs some careful study.

The effect of the X-ray upon tissue must differ from anything else, for the reason that it penetrates to such a depth, and diverges as it does so; therefore a greater area is covered below than upon the surface, while its energy is only modified by the distance from the source, and the resistance of the intervening tissue. The question of how the X-ray acts, must be overlooked for the time being, unless we accept the explanation that it is an electrochemic disturbance of the ultimate cell elements.

The inflammatory effects of the ray upon the tissues of the body have been termed a "burn," although some objection has been raised to its use, it seems to fill the sense in this instance, just as when used for an ulceration caused by some chemical. This effect may be so slight as to cause only a perceptible reddening of the skin followed by a faint tanning, there is very little

* Read before the American Roentgen Ray Society, Philadelphia, December, 1903.

local disturbance, with no systemic effects. From the work of some German authors in this field it would appear that this process closely resembles sunburn, but the effects are much deeper. In the case of severe burns, the process is unique in itself and differs from all other forms of degeneration and regeneration, although very irregular in its course. The period of incubation may be from a few hours to months, and during this time the patient may complain of severe pain in the affected part, in some instances the pain may be quite severe but intense pain does not necessarily mean a severe burn; in fact what might be termed a mild burn often produces the most discomfort. The general systemic disturbance in these cases are quite as irregular but in a general way follow the course that might be expected from ordinary ulcerations in the affected part. The first observation is that of a surface hyperemia, which is followed in a few days or even longer by a slough which gradually extends over the whole involved area. Its appearance is deceptive, it looks as if it could easily be removed but on the contrary it is quite adherent; however, after a given interval, part by part will separate and, as these pieces are removed the underlying structures have the appearance of healthy granulation tissue, but in a few days another slough will form, this process will sometimes continue for months. The appearance of the slough is like that of a bad scald, it is usually moist but differs from it in the fact that it is extremely hard to remove and will often cause intense pain. The explanation may be this, in the case of a scald the tissue dies en masse and separates en masse, while in the case of the X-ray burn the cell necrosis is only one cell at a time, the living and dead cells are intertwined, no doubt that many of these cells would recover if their nutrition was not impaired by these surrounding dead cells, and, acting like any foreign body, would also cause pain.

When the slough of an X-ray burn is carefully removed it gives the appearance of a highly magnified trabecula or a homelier simile, that of a honey comb. The line of demarcation usually seen in other forms of gangrene are practically never seen here, and even when the ulceration has greatly diminished in size by healing, these sloughs still continue to form. The scars of these burns are curious, in very severe cases where the deeper structures are involved they resemble those from fire, but the surprising fact is that when the ulceration does not go below the superficial structures practically no scar will be formed and in a month or two after the ulceration has healed the skin will be as soft and as pliable as that which surrounds it.

At this point is would be well to call attention to a membranous deposit that forms over moist ulcerated surfaces, when the X-ray is applied over a long interval of short exposures, producing only a slight amount of reaction, from its appearance it would suggest diphtheria, except that it is whiter and not so dense, although when it is removed it leaves a bleeding surface. It closely resembles the slough of a bad burn, only that the membrane is entirely superficial.

As is well known, these X-ray burns are extremely painful in most cases, yet at the same time in some instances the X-ray will relieve pain, even anesthesia of the exposed part has been observed. Several theories have been advanced in explanation of these facts, but so far we have no substantial proof. In the case where anesthesia is produced after X-ray exposures where no pathological process exists, the explanation might be, that there is a temporary degeneration of the terminal nerve filaments which causes an impairment of function. This can hardly be offered as an explanation in the case where the pain is relieved in cancer, yet it will be noticed that if these cases receive too much X-ray treatment they will suffer pain, but of a different character from the pain before treatment. These facts, however, would suggest that the effects of the X-ray must be upon the cell elements in the exposed parts. In other words, when a cancer is being treated and the X-ray is applied in sufficient quantity to relieve pain, there will be very little disturbance of the part; on the other hand, when too much X-ray treatment has been given, an active inflammation follows, which involves outside structures and pain in consequence.

The study of the effects of the X-ray upon tissue microscopically in all instances offered here has been upon pre-existing disease. It has not been my fortune to be able to procure a case of simple burn, and in most instances these cases object to the knife, therefore this study is doubly tedious. Some facts have been brought forward that seem to hold good in normal and abnormal cases, but on the other hand there still exists a great deal of mystery that seems almost impossible to explain; take, for instance, a malignant growth surrounded by healthy tissue, it is exposed to the X-ray and it simply melts away, there is very little disturbance of the surrounding tissue, not only macroscopically but microscopically as well, this is well illustrated by the following cases:

Case I.—Mrs. X., for several years has been suffering from an epithelioma of the face just above the alæ of the nose; it was at the time of treatment about the size of a five-cent piece. A section was taken from the edge of the ulceration just before the first treatment, and the microscope confirmed the clinical diagnosis. X-ray treatments were given three times a week, from an 18-inch coil, on a 110-volt current, at 3 ampères, the vacuum of the tube was about 5 inches, spark gap, the tube being 10 inches from the patient and time of exposure 10 minutes, the fluoroscope showed only a dull shadow of the hand. After the sixteenth treatment another section was removed from the edge of the ulceration, which at this time had healed to about one-third its former size. During the process of healing literally no reaction of the surrounding skin was produced and upon examination of the section very

little difference could be seen except for some slight degeneration of the cells, otherwise it was a typical epithelioma and a few weeks later, after the ulceration had healed, sections showed simply typical scar tissue. About the same observation was made in the case of Mr. S., which will be mentioned later.

Although in the reports of cases there is a wide difference of opinion as to the kind and degree of degeneration, many authors, however, speak of the vascular changes and most of them seem to agree that there is a thickening of the vessels, as was observed in the following case:

Case II.—Mr. P., carpenter, thirty-four years of age, spindle-cell sarcoma of the leg. About five years ago he noticed a small tumor over the tibia about four inches above the malleolus; at first it did not annoy him, but as the tumor grew it became painful. He refused a radical operation, but about three months before he began X-ray treatment, the mass was removed. At that time it was about the size of a split baseball, the wound did not close satisfactorily and recurrence was very rapid. At the time he began X-ray treatment several nodules about the size of marbles existed along the line of a very indurated and excavated scar, which was about 2½ inches long. They offered what would seem to be an ideal case for tissue study and it was the intention at that time to remove these nodules at intervals of every two weeks, but under daily treatment they disappeared in less than three weeks and only one nodule was removed on the ninth day. The X-ray was from a 15-inch coil, 6 storage cells, a Queen tube at about a 4-inch vacuum, the tube was about 10 inches from the patient and each treatment lasted about ten minutes. It should be said here that the ultimate result was not as favorable as might have seemed, for it recurred six months later and the man discontinued treatment. The reason for removing the section before the fourteenth day was due to the great softening and diminution to almost half the original size, there was at this time considerable erythema of the overlying skin. The sections showed considerable cell degeneration with invasion of leucocytes and a thickening of the vessels with deposits on the inner surfaces. The amount of degeneration did not seem to be in accordance with what might be expected. The vascular disturbance here was rather interesting, in a part that was rapidly diminishing, the vessels were thickened and in places were almost closed by cellular deposits, yet in the other cells there was a retrograde metamorphosis. The plugging of the vessels might explain the formation of these gangrenous patches after X-ray exposures, yet if this was the only cause, the degenerating process might be expected to subside sooner than it does, at the same time we should expect other embolic complications, perhaps these cases of pneumonia that have followed X-ray burns are due to this cause.

In another case of epithelioma of the face (Mr. S.) of thirty years' duration, sections were examined from the edges of the wound, the first section was taken after the first treatment and the other about three months later. There was very little difference between the two sections although the ulceration had closed in considerably. But while this was occurring another curious process had developed over certain areas, particularly in the deeper portions, there appeared a quite prolific growth of granulation tissue, of a pinkish color, much the same appearance that this tissue presents around tuberculous sinuses which have just been well washed with peroxide of hydrogen. Microscopical examination simply confirmed the clinical observation.

The examination of three sections from a rapidly degenerating epithelioma of the chin showed very little difference between the different sections. They were taken from the edge of the ulceration, the disease occurring in a man forty-six years of age. The X-ray in this case failed to produce any improvement, in fact it seemed to produce more irritation.

At this point it would be well to consider some of the work that has been done in this field and it will be noticed what a wide variance exists in their summaries.

Sequeira states that two definite effects from the X-rays are observed by the microscopical examination; first, a destruction of the epithelial cell, the nucleus and protoplasm undergoing lysis; in some cells there was a definite fatty change. Second, a stimulation of the connective tissue elements causing the formation of healthy scar tissue. Walker, in sections from a rodent ulcer, healing under the influence, found that a fibromyxomatous degeneration was taking place. Beck found a colloid change in an adenocarcinoma. McCaw found the same change in an epithelioma of the uvula. Ellis summarizes from the microscopic examinations of four cases: First, necrosis of cells and trabeculæ of varying degree. In Case I there was also marked fatty degeneration, fewer areas of lymphocytic infiltration in one case after exposure, about equal numbers in the others, a tendency to occlusion of the vessels by deposits on their inner surfaces, practically entire absence of infiltration by polymorphonuclear leucocytes.

In regard to this last point, Dr. Ellis's observations are rather interesting, from the fact that he has given this point very careful study. Mayou, in contradistinction to the above and like most other observers, found a large number of leucocytes, but differs from most others in the fact that he observed that the vessels were dilated. In another instance of a large tumor that had greatly diminished under the use of the X-ray, no change was noticed that could be attributed to its use.

Stewart, assisted by Nickerson, Wilson and Man, made an exhaustive study of a case of epithelioma of the hand and came to the following conclusions: (1) It is probable that when epitheliomata react favorably to the X-ray treatment that characteristic histological changes will be found; (2) the important early changes are fatty degeneration and vascularization of the epithelial

pearls; (3) leucocytic infiltration and various degeneration processes complete the destruction; (4) bodies indistinguishable from Plimmer's bodies multiply as epithelia degenerate.

When comparing the above results we find them directly opposite to those of Dr. Ellis, and the reason is due to the different clinical methods used in the X-ray treatment. In the case of Dr. Stewart no doubt there was some X-ray reaction, that is, an overaction, while in the cases of Dr. Ellis there was no great amount of reaction. This fact will be noticed in the difference between the cases of Mr. P. and Mrs. X., and Mr. S., and leucocytes might be looked upon to hold the following position: First, that they will be observed where we have an overstimulation of the parts by the X-ray; second, in cases that show no reaction leucocytes will not be observed. Allen, however, concludes that leucocytes are increased in the exposed areas immediately.

Some other points in Stewart's paper need careful attention. He refutes the statement of Unna that epitheliomata never undergo a fatty change, and as to the vascular changes he observes marked evidence of the formation of new blood vessels, noticeably in the centers of the epithelial pearls. His specimens showed no signs of an obliterating endarteritis.

Pernet examined tissue from a case of lupus vulgaris, which six months previous had received about 14 treatments about ten minutes each and given daily. He found the collagium disjointed and to some extent disintegrated, the elastin had been destroyed. The hair follicles and sebaceous glands had also disappeared, while the sweat glands showed surrounding infiltration and degeneration. A large vessel in the subcutaneous stratum showed thickened walls, and in places the upper layer of the corium showed a fibrous change.

From the above observations one would naturally expect considerable disturbance of the normal tissues, when they cover some deep growth that is being treated, especially so in the case of abdominal tumors, yet in many instances have large inoperable masses been treated, until complete absorption has taken place, and with very little disturbance of the overlying skin; no doubt that some change does take place, but it never seems to lead to any grave consequences.

The opinion has been expressed by some that all cases of malignant disease should be treated until considerable reaction is observed, but this intense reaction is not necessary, for in fact, when these cases react favorably to the X-ray they will usually do so with very little disturbance of the surrounding structures and over reaction will only lead to a necrosis of the tissues and the healing process will be delayed while the patient will suffer more pain, in some instances it has been looked upon as the cause of recurrence of the disease. Some operators advise the use of the ray until a severe burn has been produced, with the idea that it will have a good effect in retarding metastasis; this has not proved to be so clinically and when one considers the natural history of these cases, this idea is absolutely lacking in support, when we consider the limited area treated, and then, how early and how distant these metastatic processes have been found in the normal case. Sections from the case of K. G. were made from a nodule under the right axilla, the original scirrhus was of the left breast.

Another false idea exists regarding the prognosis of deep and superficial growths, the last are supposed to be much more amenable to treatment; the fact is, however, it is not the location of the disease but the form. The natural course of a superficial skin carcinoma is often thirty years; commonly fifteen years. Now compare this with the rapid progress of a breast or gastric carcinoma and an entirely different aspect presents itself; in these cases the primary process may be treated with success when a secondary process is discovered, and in rapid succession others follow, until the patient succumbs of exhaustion. Slow-growing deep growths have done well under X-ray treatment, while, on the other hand, rapid-growing superficial growths will often be irritated.

It would be impossible to review in detail all of the different phases of this subject and discuss them, but from what has been given the conclusions might be as follows: First, that no single form of degeneration is alone characteristic to the X-ray, and that the form of degeneration observed depends entirely upon the tissue exposed and the method of X-ray application; second, it would seem that the effect of the X-ray was upon the cell elements in the exposed parts, but why certain normal cells, such as those in hair follicles, etc., should be more susceptible than other tissue is still a question of doubt, but in lieu of the vascular disturbance found by many observers it might be thought that this cause plays an active part.

A HISTORICAL SKETCH OF SOME OF THE SO-CALLED CURES FOR CONSUMPTION WITH A FEW NOTES ON LATER-DAY TREATMENT.

BY J. EDWARD STUBBERT, M.D.,
OF NEW YORK.

The history of the treatment of pulmonary tuberculosis, or phthisis, is most interesting. The symptoms of this disease were recognized by Hippocrates and later, but not so clearly, by Galen. Going back one-hundred and fifty years we find that phthisis was considered a disease of a contagious nature, and, as a prophylactic meas-

ure, the Venetian laws directed the destruction by burning of the clothing and furniture of those dying of this disease. At the same time it was customary for the Sicilians to desert a phthisical patient and after his death to burn his bed and bedclothes, and to thoroughly ventilate and fumigate the apartment in which he lived. Yet Thomas, writing fifty years later, says: "It does not seem probable, however, that pulmonary phthisis is infectious; at least it is not regarded so among us at present, although Morgagni, Van Swirten and, of still later date, Morton were of that opinion."

That the character of the disease was not well understood by these earlier practitioners is evident from the method of treatment outlined and carried out by them. They treated the disease as though it were an *acute inflammation* instead of a chronic one. It is with wonder that we read of the good results obtained under some of the methods advocated. On the other hand, they recognized the value of outdoor life and exercise and advised a residence, during the winter at least, in a mild, dry, equable climate. They realized that only in the early stages of phthisis could they hope to see their efforts at treatment crowned with success, but it leads us to question their idea of incipiency when the diagnosis depended entirely on objective symptoms, no note being made of auscultatory signs. Hemoptysis was guarded against and treated as one of the causes of phthisis. As to its treatment Thomas writes: "The effusion is moderated by a strict observance of the antiphlogistic plan; by carefully avoiding heat and every kind of bodily exertion, by occasionally employing cooling purgatives, such as manna, tamarinds, phosphorated soda, sulphate of potassium, etc., and by making use of a light vegetable diet with refrigerants. As a measure not to be neglected, cold was applied to the genitals, or the feet and even the lower portion of the body was immersed. Sudden sprinkling all over with cold water or even one complete immersion was indulged in at times to stop a hemorrhage. Bleeding was resorted to if the patient "was hot, feverish, youthful and of plethoric habit with a hard jerking pulse." The operation was repeated according to circumstances. Contraindications were "marks of debility and laxity, and blood of dark color." An astringent used considerably in hemorrhages was acetate of lead gr. i-ii. Digitalis, to retard the pulse, "gave a very happy effect." Common salt and opium (for excessive coughing), in small and repeated doses were used, also hyoscyamus. If the patient was in danger of sinking from loss of blood, it was proper to apply a blister to the chest. After recovery and to prevent a return of the hemorrhage, the following regimen was the order: Small bleedings, refrigerant and cooling purgatives, strict adherence to an antiphlogistic regimen, avoiding vigorous exertions of the body, agitations of the mind, etc. Sailing, traveling in very easy carriages, swinging or riding gently on horseback were the proper forms of exercise. Bark of cinchona and chalybeates were given to persons "of lax fiber and delicate habit." These precautions were to be continued "beyond the period at which phthisis proves chiefly fatal which is usually between the nineteenth and thirtieth year."

The antiphlogistic plan, consisting of blood-letting, use of mild purgatives and a spare regimen, was considered the proper line of treatment when tubercles had formed or were about to form, although at this period opinion varied as to the efficacy of blood-letting. Thomas writes: "That blood-letting and the rest of the antiphlogistic plan may formerly have been carried too far in many cases, I readily admit; but certain it is that, for some years past, the opposite system has been carried to an equally hurtful excess." Venesection was believed to produce a resolution of the inflamed tubercles in the early stage, but not in confirmed phthisis. The diet was somewhat restricted according to the stage of the disease, as, for instance, "where the symptoms are but trifling and the patient cannot well refrain from animal food, he may then be allowed such as is of the lightest nature and most easily digested." We can readily see that those in the advanced stages of phthisis were not urged to overload their stomachs with any form of nutrition. Fermented liquors, especially spirited ones, were prohibited. Milk was found a valuable remedy, ass's milk being preferred, "whereas, to produce any effect, it (milk) ought to make a considerable part of the patient's diet. Instead of half an English pint night and morning only, as usually practised by phthisical patients, they ought to take it at least four times a day, eating a little bread with it so as to make it a kind of meal." No doubt at that time it would have been considered abuse of the digestive function to have ordered a patient to drink three or four quarts of milk daily, as is now commonly done. If the milk purged the patient, he was advised to add a little of the powder of prepared crab's claws. Women's milk was supposed to give the best results, but they found it difficult to obtain in sufficient quantity. If cow's milk was too heavy for the patient, the cream was removed. Buttermilk was largely used.

The patient was not allowed to expose himself to cold, because the physicians believed that it never failed to determine a greater quantity of blood to the lungs and other internal parts than was natural. A flannel waistcoat next the skin was recommended, and the patient instructed not to expose himself to the piercing northeast winds. They believed the tubercles to be induced and accelerated in winter and retarded in summer, which was their reason for recommending warm, mild climates for the phthisical during the cold months. They believed in the principle of amusing the mind of the patient and keeping alive the hope of ultimate recovery. With this end in view patients were sent to the hot-wells at Bristol, where, besides the waters, moderate exercises and amusements were indulged in. Some physi-

cians of the time believed the waters of these wells a specific, but to quote Thomas again: "I am decidedly of opinion that at least three-fourths of the cures attributed to all mineral waters ought rather to be placed to the account of a difference of air, exercise, diet, amusement of the mind and regulations productive of a greater temperance, than to any salutary or efficacious properties in the waters themselves." The above opinion, which holds to this day, is well borne out in the study of the advances made in the treatment of consumption from that period down to the present time.

In the advanced stages the patient was prevented from exposing himself out of doors during the winter, but they aimed to keep the temperature of his apartment at 62° or 65° F. To remove inflammation from the lungs or tubercles, blisters were applied and made perpetual by shifting them from the chest to the side and from the side to the chest. Measures that sometimes produce a good effect were issues or setons applied to the side or between the scapulæ. Topical bleeding by leeches and cupping were also practised. Factitious airs were formerly employed as inhalations, but fell into disrepute. Oxygen, considerably diluted, was regarded, in the language of the time, as "a gentle stimulus, which, by invigorating the various parts of the animal body, by communicating the firmness to the solids and energy to the fluids, does frequently obliterate the causes of morbid habits." Earth bathing and stabling with cows were recommended in cases of incipient phthisis. The vapor of spiritus etheri sulphurici dropped into warm water was inhaled "with considerable advantage to the patient." Digitalis purpuræ was held in high regard by some physicians as a new remedy in the treatment of this disease; but one writer remarks, "to speak properly, it is rather the revival of an old remedy long laid aside than a new one." Some considered it a direct sedative, others a powerful stimulant. Many regarded it as a specific.

Among other remedies used were: Hemlock in glandular affections; muriate of barytes in incipient phthisis and scrofula; mercury by a few in America. Emetics were exhibited in the early stages, two or three times a week, and considered to be "one of the most powerful remedies known" and "usually attended with a very happy effect." Cupri sulphas was the favorite remedy together with tartarized antimony and ipecacuanha. Troublesome cough was relieved by demulcents, and opiates only given when there was also restlessness at night. Hyoscyamus and humulus lupulus were employed when opium was contraindicated. Preparations obtained from the common garden lettuce, dried leaves of conium in sulphuric ether, as inhalations, and lichen islandicus were used for coughs, dyspnea, and purulent expectoration, respectively. Such was the treatment for the so-called first stage of phthisis.

For the second and advanced stages the idea was "to counteract, if possible, the effects of the absorbed matter, to mitigate the most distressing symptoms, such as cough, diarrhea, and colliquative sweats, and, lastly, to put the body in as good general health as possible by air, moderate exercises, and a proper course of mild, nutritive diet." Bleeding and purging in this stage, as formerly practised, were held to be improper methods. For frequent pulse and flushing heat caused by hectic fever, digitalis was given; uva ursi was given for the fever; and the use of emetics persisted in as advised for the first stage. Balsam of copaiba, myrrh (held in high esteem), and cinchona bark were variously administered in this stage. It was the prevailing opinion that constant exposure of pulmonary ulcers to the air prevented the healing, whereas, now we firmly believe the opposite to be true. Blisters, issues, and setons were also used in this stage, "to obviate inflammation and divert the matter." For profuse night sweats, seltzer water, mineral acids, and armenian bole were given. Some of the more advanced practitioners of a century ago, considering pulmonary consumption as entirely of a scrofulous nature, disapproved highly of the antiphlogistic plan of bleeding and a spare diet, even in the first stage of the disease, and recommended instead a nutritious diet of shellfish and animal food. The use of conium and sarsa in powder as medicines, warmth in dress by wearing flannels next the skin, heating the patient's rooms to the West Indian point (when he could not resort to a warmer climate), the application of blisters, and the frequent smart riding on horseback by way of exercise were all strongly urged.

In the last paragraph we see the light dawning on the medical men of that day as to the more complete and proper treatment of pulmonary tuberculosis. During the next fifty years we note the gradual acceptance of new and truer methods of treatment, while the old, vicious, and harmful forms were laid aside. Progress was made in diagnosis, the pathology of the disease was more closely studied, and a clearer insight gained as to the causes and course of this malady, which led to a more correct knowledge of the general treatment thereof. Just before the Civil War (1858) there seemed to be two prominent indications in the treatment of phthisis: (1) To prevent the further deposition of tubercles, and (2) to guard the lungs and the system at large against their injurious influence during their progress (Wood). To meet the first indication two objects were aimed at: (1) To correct the predisposition, and (2) to obviate the influences of the causes which excited the predisposition into action.

To correct the predisposition, exercise in the open air was considered by far the best remedy. The exercise was to be taken daily and unremittingly for months or years, and was not to be carried to the point of great fatigue, nor were the rigors of winter to interfere with it, but, properly clad, the patient was to venture out into all weathers. This was only emphasizing the need of air for consumption indicated fifty years be-

fore. "Dr. Joseph Parrish, early in his practice, observed the fatality of the modes of treating phthisis then in vogue as well as their frequently marked effect in hastening the march of the disease, and was induced to throw them all aside and return to the practice recommended by Sydenham, which advocated vigorous exercise and free exposure to the air." The patient was to be properly clothed and, when deemed necessary, the face protected by a veil. In choosing a residence, a place that was dry with a uniform temperature was selected. The interiors of Georgia, Alabama, and Florida were recommended for Americans. Excessive heat as well as excessive cold was to be avoided.

That cold climates were beginning to gain favor at this time is illustrated by the following extract from Wood: "It is a question, which experience must determine, whether the extremely cold, uniform and dry air of our high northern latitudes may not operate more beneficially on the health of persons consumptively disposed than the more relaxing climate of the south." A generous diet and the elimination of stimulant drinks, except in cases of debility, were recommended. Mental influences were to be regarded. Hygienic measures were not to be neglected for medicines, which were considered highly useful at times. Cod-liver oil came into use at this time and stood high in favor. Digitalis lost its position as a specific, but was still used for the rapid, feeble pulse. The bitter tonics were in vogue and iodine was recommended in the first stage. Blood-letting, while still practised, was no longer popular, leeches and blisters being preferred. It was deemed unwise to arrest habitual discharges or to remove long-established external diseases in the phthisical patient; therefore, fistula in ano, hemorrhoids, and external scrofulous tumors were encouraged as safe outlets of the morbid tendencies.

To obviate the effects of the tubercle in the way of cough, demulcents, opium, morphine, hyoscyamus, lactucarium, conium, stramonium, belladonna, and hydrocyanic acid were used. Dyspnea was relieved by compound spirit of ether, asafetida, aromatic spirits of ammonium, tincture lobelia, extract of stramonium, etc.

Hemoptysis.—Blood-letting was not entirely abolished, but was indicated when there was "much general excitement with a strong, full pulse." Cups, leeches, and blisters were used. The patient was kept at rest on a low diet, and such medicines as antimonials, citrate of potassa, niter, and ipecacuanha, with cooling drinks, were administered. Common salt was still given and, as astringents, acetate of lead, kino, rhatany or tannic acid combined with opium, and ipecacuanha in minute doses. Issues, setons, and pustulation with tartar emetic were less favorably regarded.

For the bronchial inflammation, tartar emetic, ipecacuanha, sanguinaria, or lobelia in small doses was advised in the early stage. In the advanced stages, they prescribed the more stimulating expectorants as the balsams, turpentines, copaiba, ammoniac, asafetida, and carbonate of ammonia; and for excessive expectoration, creosote, pyroacetic spirit, tar water, petroleum, and Barbadoes tar. Certain inhalations were in vogue for the second stage; volatile matters, as tar vapor, turpentine, and the balsams being the most popular, in addition to which trials of chlorine and iodine were made. Laryngeal affections were treated the same as chronic laryngitis. Digitalis at this time was principally employed to control frequent pulse, as were also wild cherry bark, hydrocyanic acid, and cimicifuga. For the colliquative sweats the mineral acids, acetate of lead, alum, tincture of the chloride of iron, etc., were most efficacious.

The use of emetics to cure phthisis had at this time gone out of practice, and efforts were made to prevent the occurrence of both vomiting and diarrhea. Great debility was met with a supporting treatment, although not as vigorous a one as employed to-day. To summarize the methods and remedies that were in use up to that time and either failed or dropped into disuse, we note the following: The use of emetics in the early stages; residence in a miasmatic district; exhalation from oak bark (tanners'); breathing habitually the air of stables in which were cows; inhalations of the various gases; and injections of strong solutions of silver nitrate into the air passages by means of a tube passed through the larynx. It was said that, fortunately for the patient, the majority of the injections probably passed into the alimentary canal instead of the lungs. A noted physician once told me in conversation that he had had a patient who insisted upon receiving what he supposed were intralaryngeal injections, claiming that he derived great benefit thereby. To quiet the patient, the doctor gave these injections directly into the esophagus to the perfect satisfaction of the patient and to the relief of the laryngeal symptoms.

Digitalis and hydrocyanic acid fell from the ranks as specifics, and various other remedies were laid aside. Compression of the chest and even paracentesis to induce collapse of the diseased lung were proposed, but were not practised to any great extent. In 1875, there was an increasing demand that greater attention be paid to the preservation of health and public hygiene. From that day down to our time, various drugs and methods of treatment have seen their rise and fall, while others have been improved and enlarged upon until they are now both popular and useful in combating tuberculosis. The treatment of to-day is not directed mainly at the symptoms and their sequelæ, as in former times, but the effort is made to remove the cause and to limit the further distribution of foci of disease, as well as to endeavor to prevent complications by the entrance of pyogenic microorganisms. Treatment has resolved itself into groups of remedies, most of them being external measures intended to limit the tuberculous process, to destroy or attenuate the virulency of the bacilli, and to promote an

absorption of the inflammatory products or a protective encapsulation and fibrosis of the diseased area. These methods are not to be depended upon alone, but should be regarded as auxiliaries to the first principles, namely, climate, hygiene, and dietetics combined, without which no cure can be effected. Instead of the word "climate" later developments have demonstrated that the term "fresh air" would, perhaps, be more appropriate; for the proportion of those who can afford to seek a prescribed climate to those who are compelled to receive their treatment in the home atmosphere is as 1 to 12 or about 3 per cent. And it is a fact that the fresh air, even of a large city, when obtained in abundance and in conjunction with the other two requisites, hygiene and diet, together with modern methods of treatment, has produced wonderful results. It is only within the past few years that there has been forced upon the professional mind the undeniable fact, that there is no specific climate required or to be found for tuberculars. We all know how notoriously bad, theoretically, the climate of Boston and Eastern Massachusetts is for consumptives, and yet our friends of the "Hub" are rejoicing in the statistics of the past three years, which have shown such marvelously good results in and around that much-abused district. Every practitioner knows from observation that the majority of cured cases of pulmonary tuberculosis have been cured at or near their homes, yet we still find prevalent the belief that would exile from home comforts to unforeseen hardships and discomfort every unfortunate sufferer from the Great White Plague. Perhaps one of the most valuable advancements made in the treatment of this disease is the rapidly increasing tendency to hesitate before exiling the patient, and to ascertain the special climatic requirements of each individual case before recommending a change. For example, a patient with a poorly developed left heart accompanied by tachycardia should never be sent to an elevation above 1,000 feet. Cases presenting large areas of pulmonary involvement can be more successfully treated at sea level, as are cases of phthisis colorado. Then, again, patients suffering from diabetes or kidney complications would lead a more comfortable existence not only at a low altitude but in a comparatively mild temperature. Finally, we have the incipient cases with sound organs other than the slightly damaged lungs, who do well anywhere, but for whom, if possible, it is well to prescribe either a few months' sojourn in the mountains of a cold region, or a long sea voyage.

In considering the present-day methods, it will be as well to mention the medicines intended for internal administration first, and then to enumerate and describe the plans of using the various form of light, electricity, water, serum, intravenous and subcutaneous injections, inhalations, etc. Although there have been recommended a large number of drugs for internal administration, few of them have stood the test of time and given sufficiently good results to warrant continuing their use. Even within the past decade more than forty or fifty different remedies have been used and exploited by the profession, and yet to-day there are scarcely a dozen that are even considered seriously. As far as we know, no drug has the slightest specific action in pulmonary tuberculosis. The usefulness of drugs is, therefore, restricted to symptomatic treatment. Tonics are required in all incipient cases at first, and from time to time in chronic cases of fibroid phthisis. Their name is legion, but only a few have earned a standing in the treatment of this disease. Strychnine still justly heads the list and may be administered advantageously for many months, combined at times with the bitter tonics. Antiseptics are still, and probably will always be, used extensively. Creosote, ichthyol, and cloves seem to have given the best results among the many advocated at various times. Of all the pharmaceutical modifications of creosote, I believe that none has had as strong a hold upon the professional favor as carbonate of guaiacol—eosote, geosote, creosotal and their various fellows having gradually been relegated to the use of a few. In fact, a large number of the profession still consider, and justly so, that Merck's creosote, given in emulsion or in bismuth capsules, is more efficacious than any of its derivatives. Observers are divided in opinion as to the proper dosage of creosote, but probably the majority of those of qualified judgment agree that the minimum dose of fifteen minims and the maximum of thirty-five minims, three times a day, is a safe limit. Creosote, in addition to its antiseptic qualities, is recognized as a more or less stimulant to nutrition. It seems wise to administer it at intervals rather than constantly.

Ichthyol was first exploited as a rival of creosote in Europe, and there its reputation has remained unshaken for a number of years. The best results are obtained from the administration of large doses, and if the drug is given in such form as to pass the stomach undissolved, amounts of thirty grains three times a day, are easily borne, and untoward effects are few. An occasional diarrhea or an attack of vomiting, which is preceded by the taste of ichthyol, may occur. These symptoms quickly subside upon the withdrawal of the drug, and with its resumption the dose which caused the above symptoms can usually be given without further trouble. The improvement is rapid, and within one month, in individual cases, where other beneficial factors were eliminated, there was a gain in weight of eight or ten pounds, and in those patients whose weight had previously and under different surroundings remained stationary for long periods of time. There is improvement in general nutrition, as evidenced in females by return of menstruation. The fever, sweats and cough diminish, the sputum is more easily ejected, is smaller in quantity, and changed in character from greenish-yellow to yellow, finally becoming mucoid and frothy. In some instances expectoration is too

quickly reduced, and patients experience difficulty in raising the sputa. In cases far advanced, those having a cavity with excessive expectoration, when ichthyol acts well, the effect is striking, and it is more than suggestive of the important part played by the secondary infection in tuberculous processes. Ichthyol changes the character from the fetid, decomposed, purulent sputum into that which is mucoid and frothy, ameliorates the symptoms of fever, chills, sweats and general failure of nutrition dependent upon the absorption of pus products, so that it may be said that in such cases ichthyol practically accomplishes drainage, and, what is more important, tends to convert the function of the pyogenic membrane into one which secretes mucus instead of pus. The debilitating effect of pus absorption is put aside, and there is general improvement noted. Ichthyol is one of the few drugs that have earned a permanent standing in the treatment of phthisis. It may be administered in one of two ways: In enteric coated pills containing two or five grains each, or in the form of a glycerole composed of equal parts of crude ichthyol and glycerin, of which mixture the dose would be 5i (representing thirty minims of the drug) three times a day after meals.

Among other drugs used with more or less success and which have retained a permanent position in the armamentarium of the phthisiotherapeutist are kalagua, oil of cloves, and cinnamon. Oil of cloves is administered in doses of five to fifteen minims in capsules every one or two hours, to the point of saturation. It causes less gastric disturbances than would be expected and, in the hands of most observers, has yielded very excellent results in cases of chronic or fibroid phthisis. Cinnamon is administered in doses of five to twenty minims, three times a day, but has not given such favorable results as oil of cloves. Kalagua, a drug about which very little is known except that it is an extract of the leaves of a Japanese plant, is cultivated mostly in South America. Undoubted evidence of its beneficial effect in lupus has been presented from time to time, to the profession, and the form of pulmonary tuberculosis in which it is most useful is that involving small areas, usually subacute in character, but subject to more or less regular exacerbations of all the symptoms. The instant success of antitoxin in the treatment of diphtheria led some investigators to turn their attention to the manufacture of an antitoxin or serum that might act as quickly and as efficiently in antagonizing the tubercle bacillus. The discovery of this bacillus in 1882, by Robert Koch, was the basis upon which they founded their efforts. The first product of importance was given to the profession by Koch, and was a glycerin extract of cultures of tubercle bacilli. This product was received everywhere as a sure specific for pulmonary tuberculosis, though Koch claimed to cure only those cases treated in the incipient and early stages. Its use in all stages of the disease and in too large doses soon brought about a reaction, and tuberculin was practically abandoned as a therapeutic agent while still largely used as a diagnostic one.

The new and modified tuberculin R contains finely pulverized bodies of tubercle bacilli, sterilized by being kept for several hours at a temperature of 100° C. Those observers who favor tuberculin advocate its use only in selected cases, where the focus is small and restricted to a limited area, one apex only being involved; or, if both, then but in the slightest degree. The dose should be regulated by the degree of reactive temperature, and should not be repeated until at least twenty-four hours. A method favored by some is to begin injections of tuberculin R, and, when a tolerance has been established, to substitute old tuberculin.

Following tuberculin came a serum obtained from the horse, this animal being selected as the one most resistant to attacks of the tubercle bacillus. This serum, which is manufactured by the United States Government, is prepared in a manner similar to that followed in obtaining the antitoxin of diphtheria. The idea was to find an immunizing serum, which would prevent a further development of bacilli or tubercles within the pulmonary tract. The process is to immunize a horse by injecting increasing doses of tuberculin or a similar product for several months or a year, after which time the blood is drawn, the clot allowed to settle, and the resulting serum is styled "antitubercle serum." This product, like tuberculin, has produced the best results in the incipient and early stages. The writer has reported 36 incipient cases treated, with 39 per cent. apparently cured, 55 per cent. generally improved, 9 per cent. of which were practically arrested cases. In 42 moderately advanced cases treated in like manner, the bacilli decreased in 30 per cent., weight gained in 61 per cent., and in between 71 per cent. and 85 per cent. a marked improvement of all the other symptoms was shown.

(To be Continued.)

NORMAL LABOR CONSIDERED FROM A SURGICAL STANDPOINT.*

BY A. M. POND, M.D.,
OF WEBSTER CITY, IOWA.

There is no case of common occurrence, that presents itself to the general practitioner of medicine, which requires all the demands made in a technical surgical procedure, as in an obstetrical case. It matters not how simple the case may be; if your labors are to be rewarded by anything like uniform success, there is required in each and every instance, a thorough knowledge of a perfect surgical technic. In surgical practice, success does not depend so much upon the skill and dexterity of the operator, as upon his ability to prepare his case and the degree to which he is able to make and retain surgical cleanliness.

The object aimed at in all surgery is to pre-

* Read before the Iowa State Medical Society.

vent infection, for it is an apparent fact, that no matter how skilfully a serious operation be made, success depends wholly upon the aseptic manner in which it is conducted, else we would hear the joust, "the operation was a success, but the patient died," but they forget to add, "from infection." This fling of satire could be aptly applied a few years ago, but to-day it reflects discredit, if not criminal neglect. Our labors then in obstetrics should be directed with a view to prevent infection; and this can be successfully accomplished.

When we recall the condition of the uterus immediately after delivery, with its vast bleeding surface, its large area of torn tissue, the gaping, thrombosed placental sinuses, we are at once struck with its similarity to a wound located elsewhere from whatever cause; and the frequently occurring lacerations of the cervix and perineum, when they are present, serve to make the analogy closer. And when we consider the mechanism by which the decidua is normally removed, we readily observe that a choice culture medium is prepared by nature for the reception and propagation of organisms introduced from without.

The later pathological investigations show that the diseased processes affecting surgical wounds and the puerperal genital tract are precisely similar, differing only in a slight degree by the peculiar conditions in each case. Thus we understand that puerperal fever is really puerperal septicemia, and is due to the entrance into the lacerated tract of certain bacteria which are known to have definite pathogenic properties, and right in this connection it might be pertinent to ask, how do these bacteria gain entrance? Are any of them found normally in the genital tract? Does infection always occur from the outside? Can this be prevented in every case?

Formerly it was supposed that the vagina fairly teemed with bacteria, and the theory of auto-infection was advanced, but the later investigations carried on by competent and careful observers show conclusively that the uterus is positively free from pathogenic bacteria, and in a state of health the vagina is equally so. This premise, then, meets the first argument of auto-infection. The studies of Döderlein are conclusive and must carry weight. He found existing in the vagina an anaerobic bacillus which secretes lactic acid, which is antagonistic to staphylococci, and within certain limits destroys them. He infected the vagina of a virgin with large amounts of staphylococcus cultures, and in four days found it free of injected germs. From his investigations, he formulated the following deductions: (1) All pathological secretions containing germs are weakly acid or alkaline. (2) In puerperal women the vaginal bacillus disappears and in its place are found many forms of saprophytes, and the lochial discharge becomes alkaline. (3) When the lochia ceases, the saprophytes disappear, and the vaginal bacillus reappears; the vaginal secretion becoming intensely acid.

Dr. J. Whitredge Williams supports Döderlein's deductions, after continued observation and a study of other investigators. Kronig made two hundred examinations of vaginal secretions, and failed to find pathogenic microorganisms. He attributes the sterility of the vagina to the outward flow of the vaginal secretions. Menge thinks the germicidal action is aided by the anatomical elements of the vagina, and holds that there is a marked leucocytosis due to the irritation of the vaginal wall, and that this is followed by subsequent phagocytosis.

Having sufficiently considered the uterus and vagina, let us inquire into the state of the vulva. Dr. J. Clifton Edgar, of New York, gives us a careful bacteriological study of this region by a series of results found in examining the vulva of pregnant women; of thirty cases examined, he found the staphylococcus eight times; *Staphylococcus aureus* three times; streptococcus once; sterile nineteen; *Bacillus coli communis* none.

This table shows presence of pyogenic bacteria in about 40 per cent. of the cases he examined. This report is very valuable to us, since it gives a clue concerning the location of the infective agents. This has been used in support of the auto-infection theory, but can scarcely be given much importance in that relation, when we consider the fact that the vagina is the only route from the vulva to the uterus. We have also found that the vagina has certain bactericidal powers in health; but we have also seen in the foregoing that in the puerperal state the secretions of the vagina become alkaline, and as the sterility of the canal is dependent upon the acidity of the contents, we find that instead of there being any defense for the culture of pathogenic bacteria, it has become a perfect culture medium for them. Dr. Matthew D. Mann, of Buffalo, ascribes the alkalinity of the secretions after labor to the large amount of blood serum which is poured out, and to the absence of the *Bacillus vaginæ*, which seems to be destroyed after labor.

As another argument against the theory of auto-infection, we might mention the results of douching before and after labor. It would certainly seem that if the vagina contained pyogenic bacteria antiseptic solution of proper strength, would give better results than where the douche is omitted. Just the opposite of this, however, is true as shown by the labors of Leopold. He used the douche faithfully and well in 5,784 cases, and in $17^{6}/_{10}$ per cent. of this number there developed an infection. In another series of cases he confined 4,088 women and without the douche at an time during the puerperium and had infection in but $7^{8}/_{10}$ per cent., or a decrease of nearly 10 per cent. Undoubtedly the greatest argument in this matter is the results obtained by several large hospitals in this country, where great care is given to the patient and surgical cleanliness is thoroughly maintained, and in my opinion these reports conclusively prove the fallibility of the auto-infection theory, because if such a thing as

auto-infection were possible, then these results would be impossible, since a certain proportion of these cases would be infected, notwithstanding the greatest care. Following is the list: Sloan Maternity, no mortality from sepsis since its foundation. New York Maternity, 1,321 cases; no mortality from sepsis. New York Post-Graduate, 850 cases; 1 death from sepsis. New York Polyclinic, 450 cases; no deaths from sepsis. Preston Retreat, 480 cases; no deaths from sepsis. Boston Lying-in Hospital, 2,194 cases; 1 death from sepsis. University Hospital, Philadelphia; no deaths from sepsis in nine years.

The foregoing certainly reflects great credit on these institutions. Especially is the work commendable in those hospitals wherein there has occurred a death from sepsis, and the case was successfully isolated and was not communicated to other patients. This speaks volumes for their aseptic preparation, for it is generally accepted that sepsis is contagious by inoculation, and only rigid preparation can prevent it.

In 1847 Ignatius P. Semmelweis, at that time an assistant in the Lying-in department of the Vienna General Hospital, endeavored to find the cause of the high mortality rate that existed in his service. He was not slow to discover that this high rate was greatest in the Students' Clinic. These men were constantly engaged in dissecting, and at the same time pursued their studies in the Maternity wards, without any special cleansing of their hands. At this time nearly 10 per cent. of all the women confined in this branch of the service died from infection. In the Midwives Clinic the mortality was but about three per cent. Prolonged or complicated labor in the Students' Clinic was invariably fatal, while in the Midwives Clinic, the length of time or the occurrence of complications did not materially increase the death rate. He also noticed that women who had been delivered before admission and even when unattended, escaped infection. About this time one of the professors died from an infection received during dissection, and the symptoms presented by his associate were so similar to those who were dying in his service that he thought it was more than a mere coincidence, and sought the cause. He began by requesting the students to thoroughly wash their hands in chlorine water, and restricting the number of vaginal examinations. This action was promptly followed by a rapid decrease in the mortality rate, and in a very short time the death rate of that service was less than two per cent.

Thus it was that Dr. Semmelweis gave the world the pioneer work in modern obstetric asepsis and antisepsis, although he did not give it this name. His work has been faithfully carried out and enlarged by such men as Holmes, Lister, Tait, Döderlein, Williams, Edgar, and others familiar to all present.

The work done by the earlier men in this line was not well received. The entire profession hooted at the idea advanced by Semmelweis. He was made a target of ridicule and malignant opposition, and, being a sensitive soul, fretted himself insane. He could not stand the criticism advanced after, when he had such ample proof of its authenticity, and curiously enough, he died of an infected wound received during a septic operation, just in time, however, to prevent the humiliation of being committed to an insane asylum.

The honor of advancing these ideas in America belongs largely to Dr. Oliver Wendell Holmes. In 1843 he wrote an article in which he states that "child-bed fever is a contagious affection, and is preventable and owes its origin to either the attendant or nurse." These views were not accepted, and exerted very little, if any influence, at the time. They were rigidly opposed by the eminent men of the times, especially by Meigs and Hodge, of Philadelphia; Meigs declaring that he preferred to believe that puerperal infection was due to the workings of a Providence, which he could understand. It is strange that both Semmelweis and Holmes experienced the same opposition, when each had labored so faithfully and well to serve mankind by robbing it of one of the greatest horrors assailing that sacred state of motherhood. At the meeting where Holmes read his second article, the discussion brought out a torrent of abuse and ridicule and, headed as it was by such men as Hodge and Meigs, it can be readily understood how men of lesser degree ventured opinions furthering the abuse, since they considered the leaders of the discussion paragons of medical learning. The condition then was very much as it is to-day; each man has a certain following. Holmes' reply to them will always be considered a classic, and I feel that I can well afford to take time here to quote it to you. Addressing the Chairman, he said: "I have no wish to express any harsh feeling with regard to the painful subject which has come before us. If there are any so far excited by the story that these dreadful events that they ask for some word of indignant remonstrance to show that science does not turn the hearts of its followers into ice or stone, let me remind them that such words have been uttered by those who speak with an authority I could not claim. It is as a lesson rather than a reproach that I call up the memory of these irreparable errors and wrongs.

"No tongue can tell the heart-breaking calamity they have caused; they have closed the eyes just opened to a new world of love and happiness; they have bowed the strength of manhood into the dust; they have cast the helplessness of infancy into strangers' arms, or bequeathed with less cruelty, the death of its dying parent. There is no tone deep enough for regret, and no voice loud enough for warning. The woman about to become a mother, or with her new-born upon her bosom, should be the object of trembling care and sympathy wherever she bears her tender burden, or stretches her aching limbs. The very outcast of the street has pity on her sister in degradation, when the seal of promised maternity is

impressed upon her. The remorseless vengeance of the law brought down upon its victim by a machinery as certain as destiny, is arrested in its fall at a word which reveals her transient claim for mercy. The solemn prayer of the liturgy singles out her sorrows from the multiple trials of life, to plead for her in the hour of peril. God forbid that any member of the profession to which she trusts her life, doubly precious at that eventful time, should hazard it negligently, unadvisedly or selfishly."

Passing now from the discussion of auto-infection, we will briefly consider the forms and the source and character of the pyogenic bacteria introduced from the outside.

By far the commonest source of infection is produced by the saprophytes. These are organisms developed on decaying matter. They abound in the feces of parturient women, and find culture material in the blood clots, bits of placenta and membranes. They cannot be said to be truly septic in their action; theirs is rather a rôle of decomposition, as they do not at any time enter the circulation, but produce certain toxins, which in turn give rise to certain symptoms. They are mostly of an anaerobic nature, and cannot be cultivated on the ordinary culture media, and no doubt consists of many forms, which as yet have not been identified; hence, the term saprophytes is a general one, and does not signify any certain forms of bacillus.

Their action on the uterus and vagina is equally vague and obscure; many of them are gas producers, and give rise to the frothy and foul-smelling secretion present in these cases. We can well understand how thoroughly Semmelweis conducted his labors in this direction by reviewing an article published by him just before his death, in which he states:

"The bearer of the decomposed animal-organic material is the examining finger, the operating hand, instruments, foul bed-clothes, impure air, sponges, etc. In other words the bearer of the decomposed animal organic material is anything which is soiled by a decomposing animal-organic material and afterward comes in contact with the genitals of these patients."

While these saprophytes then are local in their action, the state of lowered resistance, induced by their presence, makes it a most favorable condition to be followed by a true septic infection, and while the condition of sapremia may be easily controlled, if a true septic condition should develop, then it would become a grave state indeed.

The true pyogenic organisms that cause infection may be briefly summed up as follows: Streptococcus, the usual cause of the fatal and epidemic form, produces no evidences of decomposition, the discharges are much lessened in amount or entirely absent and free from odor, reproduces itself very rapidly, and extends along the lymphatic routes, gains entrance into the peritoneum and gives rise to symptoms of general sepsis. Staphylococcus is usually associated with the streptococcus, thus giving us a mixed infection. The *Staphylococcus aureus* is the usual form observed in the infection of this condition, while the *Staphylococcus albus* and *Staphylococcus citreus* play little or no part in its production. However, it may be well to state in this connection, as Williams has pointed out, that while the streptococci are usually the causative agents in puerperal infection, they are not necessarily the only organisms concerned in its production, it being clearly shown that most of the pus-producing organisms found in wound infection may also be found in puerperal infection. Gonococcus causes a mild infection when found alone and unmixed. Krönig was able to cultivate gonococcus in 50 out of 179 cases, presenting a mild febrile course. None of these cases resulted in death. *Bacillus coli communis* is mild in its action in this location. Vignal states that one decigram of feces contains about twenty million of colon bacilli, and when we consider the close proximity of the parturient canal to the rectum, sometimes bulging by the pressure of the head downward, and the practice of some men to assist the delivery by passing a finger or two into the rectum to make pressure, we can readily understand how obstetrical asepsis can be compromised.

The foregoing are the commonest forms and I will not weary you by a recital of the other bacillus found, further than to merely mention them: Klebs-Löffler, pneumococcus, *Bacillus aerogenes capsulatus* or gas bacillus, and *Bacillus typhosus.*

Thus we have found in the foregoing that the uterus after labor presents exactly the same condition as a surgical wound; that the diseased processes affecting surgical wounds and the puerperal tract are identical; that the uterus and the vagina in the pregnant state are sterile and possess certain bactericidal powers; that the vulva lodges pyogenic organisms; that the vagina with its outward flow acts as a barrier to the introduction of these organisms into the uterus; that these organisms, then, are introduced into the tract from the outside; that any decomposed animal-organic material should be rigidly excluded.

Therefore, we are now ready to take up the study of how these morbid conditions can be prevented, as the consensus of opinion among the men giving this subject the greatest thought, lead us to believe.

If there is anything which the preceding study proves beyond the question of doubt, I certainly believe it is this: In the point of technic, the practice of obstetrics is a surgical procedure. The time to save your patient's life is when you are preparing her for, and during confinement, not after the infection has taken place, for then your efforts will only too often be rewarded by failure and we will hear the refrain of the mournful note sounded by Dr. Holmes in that memorable reply to his cruel critics.

In beginning this crusade against infection, one of the most important necessities is the educa-

tion of the patients to secure their attendant some little time before confinement, in order that the room and the other essential matters of preparation may be attended to in ample time, thus eliminating the danger by hurried preparation.

The room, if one can make a selection, should be light and capable of being freely ventilated, and the bed placed so that this may be accomplished without subjecting the patient to exposure to drafts.

Do not shut out the sunshine. Sunshine is God-given and is valuable. Lots of it, however, goes to waste for the lack of proper appreciation. Sunshine in itself is a bactericide of no mean potency, besides it adds much to the cheerfulness of the lying-in chamber. Arrange the windows so that the direct rays are not in the eyes of either mother or child, but by no means exclude it altogether.

The furniture should be simple and plain; the bed should be arranged so that the attendant can approach the patient from either side; the bed linen should be fresh and clean and a simple hard mattress answers the purpose of confinement best. No feather-bed should be tolerated, as they are animal-organic material, besides being unsanitary.

When the engagement is made sometime previous to the expected time, have the patient secure about two yards of white table oil-cloth; this is to be carbolized at the time of labor, and a blanket or quilt rolled tightly from end to end and pinned in the shape of a horse-shoe and placed transverse the bed, the oil-cloth laid over it, arranging the depression in the quilt so that the hips may rest therein. This will place one of the edges of the folded quilt under the back and prove a very grateful support to the tired back. The other edge of the roll is far enough from the vaginal outlet so as not to interfere with the delivery of the child. The loose ends of the oil-cloth are then gathered into a suitable vessel at the edge of the bed. Thus we have an arrangement that is capable of being made more aseptic than a Kelly or a Morrison pad, and at the same time eliminates the grave danger of carrying infection from one case to another, and another great recommendation is the small expense.

It is well also to instruct the family to have four towels securely wrapped in unbleached muslin, and thoroughly baked in the oven of an ordinary cook-stove for about an hour, then laid away for use during the confinement. This process quite effectively sterilizes them, and wrapped as they are, they will remain so until needed. A couple of washbowls will be required, but in the emergency two ordinary basins will answer the purpose, providing they are clean.

The patient is prepared, when possible, by a thorough bath, rectal enema and catheterization; where it is impossible to attend to the bath, by no means neglect emptying the bladder and especially the rectum, for, should involuntary evacuation of the bowel take place by reason of the pressure exerted by the descending head, the previous preparation counts for nothing, and extreme care will be required to prevent an ensuing sapremia, due to the action of the colon bacillus, hence it is altogether safer to attend to this matter deliberately than to be compelled to meet it in emergency.

The woman should be attired in a fresh clean nightrobe, and this can be rolled or folded up in under her arms, and an old but clean skirt snugly pinned about the patient just above the waist line. Thus after delivery, by the removal of the soiled skirt and our improvised confinement pad, we have our patient in a clean bed, with clean clothing without disturbing the peaceful rest so highly prized after a long and tedious painful labor.

The attendant should be gowned in a white sterile gown which answers the double purpose of preventing his clothing from being soiled, as well as protecting the patient from a possible infection from dust and other material that could arise from contact. It also adds much to the aseptic completeness of his work. I will mention the preliminary vaginal douche, only to condemn it. The studies of Leopold and others so conclusively prove that it is a dangerous procedure, and is only permissible, where, after a bacteriological examination of the vaginal contents or the secretion, is found to contain pyogenic organisms, and right in this connection let us consider the vaginal examination. Just so long as vaginal examinations are made, no matter how carefully we attempted to disinfect our hands, or the vulva, infection will occasionally be met; this is due to the fact that it is a very difficult matter to thoroughly sterilize the hands, together with the fact that the vulva not infrequently harbors pyogenic organisms. It is to be desired, therefore, that we limit the number of vaginal examinations as much as possible. Little is to be gained from the vaginal examination except to determine the degree of dilatation of the cervix, and thus to make an estimate on the probable duration of labor. Leopold has advanced the idea that labor is best conducted by doing away with the vaginal examination altogether, and relying wholly on the external examination, claiming that the position can be determined with greater accuracy than by the vaginal route, and thus eliminating the grave danger of infection by either the finger, or contamination from the vulva. One of the very first precautions taken by Semmelweis, we remember, was to lessen the number of vaginal examinations. The average accoucheur makes altogether too many of the examinations, and I have known men to sit with their finger in the vagina during almost the entire second stage of labor, believing that they materially assist in dilating the cervix; perhaps they do, but the danger they take by infection greatly overbalances the good that they believe they are doing. The external examination has much to commend it. It is perfectly harmless, and can be made as often as desired, and, unlike

vaginal examination, requires no hand disinfection.

There is a great diversity of opinion as to the best methods of hand sterilization. Some men even go so far as to state that the use of antiseptic solutions are of no value whatever. In a very interesting paper on this subject, Dr. Edward R. McGuire, of Buffalo, has given some very practical suggestions regarding the disinfection of the hands, and has faithfully carried out some very convincing experiments. He closes his article by summarizing as follows: (1) Absolute sterility is impossible by any method. (2) Long-continued vigorous mechanical scrubbing frees the skin of the larger numbers of bacilli. (3) The use of the ordinary solutions for antisepsis is questionable, and under usual conditions distinctly harmful. (4) The use of rubber gloves approaches the ideal. Dr. Wm. J. Mayo, of Rochester, Minn., declares that by scrubbing the hands, we destroy the natural protection that has been provided for harboring of the bacilli, and thus make them more in evidence. He advises and uses the mere thorough washing of the hands in a lather of castile soap and does not touch a brush to the surface. Dr. Joseph Price, of Philadelphia, some time ago suggested the use of ordinary mustard flour, used with green soap rubbed into a paste. The water frees the valatile oil of mustard, which is known to be the most effective vegetable antiseptic known. Dr. Roswell Park has added to this the ordinary corn-meal, previously sterilized. This acts as a mechanical aid to the mustard paste and gives it unsurpassed utility, since it is not severe enough to destroy the outer layer of the skin which protects the resident bacilli.

Personally I prefer this to any other method. It does not leave the surface of the skin rough, it is usually found in all households, and it is efficient in obstetrical work. However, it is well to substitute some of the liquid preparations of soap for the green soap. When you carry your soap in a bottle, you cannot get your hands into it to infect it. This cannot be said of the other forms.

Before preceding with the vaginal examination, then, prepare your hands in the manner best suited to your own ideas, since there is no positive means of securing sterility. In emergency of precipitate labor simple washing in ordinary yellow kitchen soap with plenty of hot water is far better than no preparation at all. The vulva should be thoroughly cleansed by the nurse while the attendant is preparing himself. This should be done with every care, remembering that it is the material that is carried in from the outside that produces the unfortunate complications, and the best and easiest way out of the difficulty is to prevent their occurrence. After the hands and vulva are cleansed, I use a gauze pad, with a slit in the center, to protect the vulva while the finger enters the vagina. These pads are made of four thicknesses of gauze, about eight inches square, and are wrapped in packages of eight and sterilized, then carried in my obstetric bag for use. The nurse places one of these bags snugly in the vulva, and the examination is made through the slit in the center. In this way the parturient canal is protected from the usual source of infection so far as the mother is concerned.

After delivery the placenta should be expressed, there being no occasions to introduce the fingers again into the vulva or vagina, and as the route of expulsion is outward there is no danger of infection from that source, unless the hand or fingers are introduced, and this will not be necessary, unless there is an adherent placenta. In that event the entire arm to the elbow should be prepared thoroughly and the placenta removed.

The responsibility does not cease with the termination of labor. Every precaution should be taken to secure a tranquil puerperium. The napkins to receive the flow should be sterile, and clean cloths, which have been boiled and ironed are sufficiently sterilized to answer the purposes, as the flow is outward, and infection is not likely to occur. When it can be arranged it is best to have pads made of absorbent cotton enclosed in layers of gauze; these can be sterilized and after using, destroyed, as the expense is small and it is much more positive and adds to the surgical completeness of the after-treatment.

The care of the child is not less, in proportion, than that of the mother. There are certain responsibilities that will reward the attendant if well and aseptically performed, and the penalty for neglect is correspondingly simple or grave, as the case may be. Of course no obstetric attendant would neglect the eyes of the infant in this age, but there may be temptation to neglect the surgical technic regarding the cord, and grave complications follow neglect here, a case occurring in my own practice will illustrate the danger.

Charles Edgar, a full-term child, and delivered after a very brief labor, no instruments, eyes washed in weak sterile boric solution, and cord dressed with plain sterile gauze, when ten days old had a black movement of the bowels of the consistency of tar. Examination revealed pneumonia of both lungs, temperature 166° F., the umbilicus discharging and bleeding slightly. The umbilical depression was irrigated with a 1 : 2,000 solution of bichloride and dressed with iodoform gauze. The pneumonia treated with a cotton jacket and stimulation, and with lessening of the umbilical discharge the pneumonia subsided. This undoubtedly was a case of septic pneumonia; other phases of umbilical infection may be mentioned such as meningitis, inflammation of the umbilical vessels, peritonitis, osteomyelitis, arthritis, erysipelas and abscesses in the cellular tissue. Thus we see that pyogenic infection of the infant, like infection of the mother, is a preventable disease, and its presence is invariably due to some failure to execute the proper surgical technic in connection with the delivery. The statistics of the Moscow Lying-in Hospital, published by Miller in 1888, show that previous

to the introduction of aseptic and antiseptic methods, from six to eight per cent. of all the infants died from some of the many varieties of infection and that over eighty per cent. of these infections could be traced to the entrance through the umbilicus. Quite in contrast to these figures the Sloan Maternity Hospital, in New York, does not report a single marked case of infection of the infant since its establishment.

From this comparison it will be evident that in the vast majority of cases the occurrence of infection is due to the negligence of either nurse or attendant.

The umbilicus then should be treated like any other fresh wound, and with all the surgical care

The umbilicus, then, should be treated like any that would be given a surgical wound. Their similarity is striking, only differing as to the cause and location. Dry dressing should invariably be used, and this should be positively sterile. There should be no doubt of this and a simple manner of carrying sterile dressings for the cord is to keep a small jar of sterile gauze sponges in the obstetric bag and use them with sterile hands in making the umbilical dressings. Around this can should be wrapped absorbent cotton, but the practice of wrapping absorbent cotton direct from the commercial package is dangerous, and infection following is due to criminal negligence. Should suppuration occur in spite of all precautions, the wound is irrigated with a solution of bichloride in the strength of from 1:2,000 to 1:3,000, then dusted with iodoform and packed with gauze; or, instead of dusting apply the iodoform in the form of gauze, but by no means use both, as the danger from iodoform poisoning is grave and children are peculiarly susceptible to this idiosyncrasy. The ligatures and everything that comes in contact with the abraided surface of the umbilical region should be thoroughly sterilized, and every precaution taken as in the dressing of a wound.

In closing, then, permit me to recapitulate, under the following heads:

1. Success in obstetrics depends wholly upon your ability to secure and retain surgical cleanliness.

2. The same infective agents encountered in surgical practice are the causative agents in producing puerperal complications, and are only successfully combated by the employment of stringent aseptic and antiseptic technic.

3. Refrain from making numerous vaginal examinations, and when done, execute great aseptic care.

4. Do not wait until you are called to the case to make the preparations for confinement.

5. The practice of carrying a confinement pad is dangerous.

6. Sunshine in itself is a valuable germicide; do not exclude it.

7. Unless the vaginal discharge is known to contain pyogenic bacteria the douche is contraindicated.

8. Exert the same surgical technic in dressing the umbilicus that would be demanded in any other fresh wound.

9. Be clean and be sure that you are clean. Take no chances. By so doing you will reap a liberal temporal reward, besides having the serene satisfaction of knowing that you are serving humanity faithfully and well.

RUBBER CUSHIONS FOR GENERAL SURGICAL, GYNECOLOGICAL AND OBSTETRIC USE.

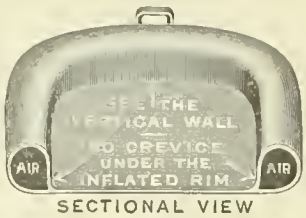
BY HOWARD A. KELLY, M.D.,
OF BALTIMORE, MD.

It is now seventeen years since I first described my Perineal and Ovariotomy drainage cushions (see *American Journal Obstetrics*, 1887, p. 1029); the following year I added a cushion for general surgical purposes (*New York Medical Journal*, April 28, 1888), and again in 1892 (*New York Medical Record*, Dec. 3) I described the obstetric cushion. Since then these simple aids to our surgical technic have proven sufficiently valuable to come into world-wide use, constantly taking the place of specially constructed tables in extemporized operations, and obviating the necessity for attachments to the regular surgical tables by providing effective drainage from the wound area to the receptacle on the floor. They are of constant service in saving the patient's person from being soiled beyond the field of operation, as well as in protecting the under clothing and night dress, and shielding the beds and sheets from contamination.

The cushions in use up to the present date, while affording efficient drainage, have been open to the objection that they are difficult to clean in the narrow recess of the apron under the rounded rim. I sought to meet this difficulty about fifteen years ago by attaching the rubber apron at the middle of the rounded rim, so that the cushion could be used with either side up, and I then had a cushion made after this pattern by a well-known firm dealing in rubber goods in Philadelphia, but it did not prove satisfactory, as it was too shallow, and I abandoned it.

The lingering objection to the earliest styles of

Fig. 1.



SECTIONAL VIEW

drainage cushions has at last been obviated by Meinecke & Company, of New York, manufacturers of advanced specialties for hospitals, by constructing the inner surface of the inflated rim in the form of a vertical wall, which joins the floor of the cushion at a right angle, as indicated by the arrows in sectional cut (Fig. 1). In this

way, while all the depth of the original cushion is kept (and even slightly increased), no part

Fig. 2.

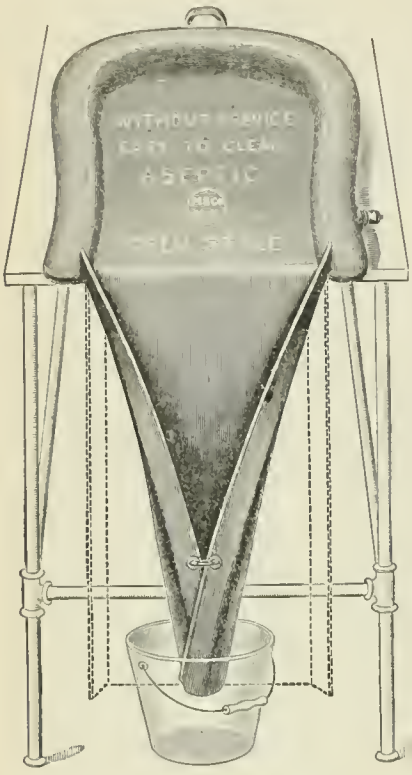


Illustration shows how drainage-apron may be hooked together, thus forming a closed outlet-sleeve. The drainage is thereby carried directly into the receptacle, instead of over the floor and on the operator's clothing.

The dotted lines show how drainage-apron hangs when not hooked together. Notice the gutter or protection, shown by dotted lines, which is formed on each side of the drainage-apron, thus preventing the fluid from running off the sides of apron when used hanging straight down, in the position shown by dotted lines.

Fig. 3.

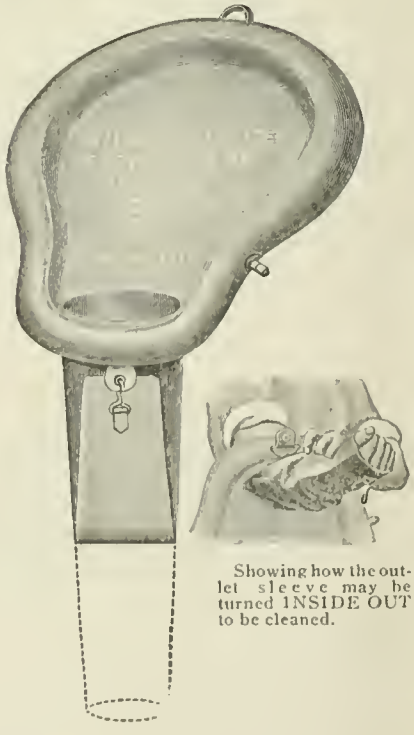

Illustration shows how outlet sleeve may be hooked up, thus forming its own receptacle. This makes a drainage pail unnecessary in operations in which there are less than two quarts of fluid present.

Dotted lines show how outlet-sleeve may lead into drainage pail during operations where there are upward of two quarts of fluid present. The outlet-sleeve is *closed*, like the sleeve of a coat, thus carrying the drainage into the receptacle instead of over the floor and on the operator's clothing.

Showing how the outlet sleeve may be turned INSIDE OUT to be cleaned.

is concealed from view, there is no crevice, and perfect cleanliness is possible.

The small square cushion of this pattern, commonly called "perineal" size, is 15 inches wide; the standard operating size is 20 inches wide, and a large operating size is made 24 inches wide. The 20-inch size is the one most generally used (see Fig. 2).

The obstetric cushion is made with a reversible closed sleeve, which hooks up to the rim in such a manner as to catch amnion, blood and placenta, which collected in this pocket can be transported to the bathroom, weighed and inspected, without the use of any other vessel (see Fig. 3).

In using the cushions for gynecological and general surgery, it is best to lay a sterilized towel between the cushion and the patient. I would also use a sterilized towel or gauze in all obstetric cases. My own practice is to consume from one-half pound to one pound of sterilized absorbent cotton in each obstetric case, unrolling and tearing off a good handful of the cotton at a time, and stuffing it between the buttocks below the vulva. When a wad is saturated or soiled, I drop it into the receptacle formed by the apron and substitute another piece. In this way the patient is kept clean throughout. A proper use of the obstetric pad quite does away with the customary washwoman's tax (sometimes as much as $5.00 for a single wash), which she often levies for handling the soiled linen after the arrival of a baby.

I am in the habit of sterilizing my cushions by soaking them for twenty-four hours in a bichloride solution 1-1,000, or even 1-500. This has never seemed to hurt the rubber; the valve of course must be kept out. If there is much odor clinging to the rubber, Labarraque's solution will correct it.

MEDICAL PROGRESS.

MEDICINE.

The Blood in Pneumonia.—The contradictory results reported by investigators with regard to the finding of the pneumococcus in the blood of pneumonia patients led F. C. Kinsey (Jour. Am. Med. Ass'n, March 19, 1904) to make a new series of examinations. Fifty cases were examined, the blood being taken from one of the veins at the bend of the elbow under the most careful aseptic precautions. In answer to the question whether pneumococci could be found in the blood at any time, the cultural and other tests afford an affirmative answer. In one series of 25 cases, there were only three positives but in another series of 25, under more favorable conditions of growth, there were 19 cases with a positive result. It is possible that the negative results were due to unfavorable conditions of growth. The best results were secured with large quantities of blood (3 to 6 c.c.) with a dilution of over one to twelve of a liquid culture medium, preferably bouillon. He believes that the mere finding of the pneumococcus in the blood is of no prognostic importance whatever. Of the 19 positive cases in the second series, 69 per cent. recovered and 31 per cent. died, while of the negative cases, 33 per cent. recovered and 67 per cent. died. No worse prognosis seems to attach to a positive than to a negative finding. He found, however, that where the cocci were present in large numbers the prognosis was always grave.

Excretion of Oxalic Acid, etc., in Diabetes.—The amount of oxalic acid in the urine of diabetics is not regularly increased but W. v. Moraczewski (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6) obtained high figures more frequently than in other conditions. The influence of diet is somewhere different than normally for the addition of meat increases the amount in severe cases. With a strictly fatty diet and after the ingestion of calcium salts, oxalic acid, the conjugated sulphuric acids and indican are freely excreted but a distinct relation between oxalic acid and sugar is not always present. Both oxalic acid and acetone fall in amount after every change of diet, are influenced alike when phosphate of lime is given but after vegetable diet, the amount of oxalic acid, indican and conjugated sulphuric acid falls, while that of acetone rises. In all cases, the urine was rich in indican, and, after milk diet, in ammonia, especially after calcium. Urea and uric acid were found diminished and chlorides increased, especially after vegetable diet. There does not seem to be anything specific in the high amounts of oxalic acid, for the author has obtained equally high and even higher figures in hepatic disorders.

Proteids in the Urine of Nephritis.—A. Calvo (Deutsch. Arch. f. klin. Med., Vol. 51, Nos. 5 and 6) draws attention to the interesting fact that every albuminous urine will throw down a precipitate with acetic acid in the cold, if properly diluted. The amount varies and a large amount of albumin does not necessarily mean a heavy precipitate. The investigation of the character of this precipitate was a difficult task, but it probably consists of euglobulin and fibrinoglobulin in some cases and of serum albumin and pseudoglobulin in others. The occurrence and amount of serum albumin plays no constant rôle in the different forms of albuminuria but euglobulin and fibrinoglobulin are very abundant in febrile albuminuria and scarce in interstitial nephritis. The reverse holds true for pseudoglobulin: it is scant in febrile albuminuria and abundant in chronic nephritis. After dialyzing, every normal urine, free from albumin, will also give a precipitate with acetic acid in the cold, which consists chiefly of euglobulin and fibrinoglobulin.

The Problem of Glycolysis.—It is generally conceded that glycolysis is a specific fermentative process, but there is still considerable divergence of opinion as to whether the glycolytic ferment is performed in the cells and rendered active by a substance secreted by the pancreas or whether the ferment can only result by the combination of cellular with pancreatic elements. The experiments of A. Braunstein (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6) prove, however, that pancreas is not necessary to bring about a splitting up of sugar, for a rapid glycolysis was obscured if liver and coagulated blood were digested for some time with a sugar solution. The action of the ferment is very strong at first but is soon inhibited by the presence of carbon dioxide and acids The concentration of the sugar solution also seems to have an influence upon the rapidity of the process. The ferment is probably contained in the leucocytes; this would explain why a pneumonia or a suppurative cystitis will be followed by a reduction of diabetics.

Studies on Dysentery and Typhoid.—The bacteriology of dysentery is still a complicated one, especially since D. Jürgens (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6) carefully studied an epidemic in a small town. By many the bacilli of Kruse, Schiga and Flexner are considered identical but the germ isolated from the stools of almost all cases by the author, while morphological and in culture it closely resembled the Kruse bacillus, agglutinated only the blood-serum of an animal treated with the Flexner germ, so that the two must be looked upon as different species. The culture medium of v. Drigalski-Conradi has proven especially valuable; upon it the dysentery bacillus forms blue, transparent colonies resembling those of typhoid, while the growth of most other germs, except the colon bacillus, is inhibited. The agglutination test is not absolutely conclusive since all the members of the dysentery group agglutinate each other to a greater or lesser extent but the text is generally positive in high dilutions only with the specific cause of the disease. Pfeiffer's phenomenon, that is, the disintegration of the bacilli, if introduced into the peritoneal cavity of a guinea-pig together with the serum of a patient, cannot be resorted to in dysentery as in typhoid. In the former disease, the specific agglutination appears during the first days of the disease, reaches high degrees by the second or third week (1-100 to 1,000) and gradually falls by the second month. But it seems that the serum of patients suffering from other diseases also has some agglutinating power, thus 1-30 was positive in six cases of pneumonia, scarlet fever, measles and sepsis and even 1-200 in typhoid. It is thus evident that only high dilutions possess diagnostic value. During the epidemic a large number of individuals also suffered from an apparently innocent intestinal catarrh which was caused by the same germ, since the blood-serum regularly agglutinated though not in as high a dilution as where the discharge was bloody. The individual reaction plays an important rôle and it is even possible for perfectly healthy individuals to discharge so large a number of pathogenic dysentery bacilli, that multiplication must have taken place in the intestines. Outside of the germ and the degree of personal resistance, a third unknown factor is active in keeping up and prolonging an epidemic, for if all the diseased and those about them are moved to some other locality, the epidemic frequently comes to a sudden stop. In a second article (Zeitsch. f. klin. Med., Vol. 52, Nos. 1 and 2) reference is made to the fact that even typhoid bacilli have been found in the excreta of healthy persons. The paratyphoid problem is also discussed and the confusion caused by the group agglutination makes it evident that a bacteriological examination of the feces must now supplement the Widal test. Cases of supposed mixed infection with typhoid and paratyphoid germs must be regarded with suspicion, for almost every paratyphoid serum will clump typhoid and allied germs in suitable dilution. Clinically, paratyphoid differs very little from true typhoid; like here, there are mild, severe and atypical cases and without a bacteriological examination, the differential diagnosis can never be made. The complications too, are the same, and in the few cases which have come to autopsy, typical typhoid ulcers were found in the intestines together with the other, characteristic lesions of tphoid. The germ also occurs in the blood and roseolæ of paratyphoid cases and occasionally in the feces of healthy individuals. The mode of infection is still in doubt and it is probable that other factors beside contact infection are at work, though the source is unknown. With our present knowledge, a diagnosis of paratyphoid is only admissible if this germ is found in the feces without the typhoid germ, if it agglutinates in high dilution with the respective serum and if Pfeiffer's experiment is positive. But with every epidemic, paratyphoid bacilli may occur in the stools of patients suffering from some other disease, such as influenza or tuberculosis, so that with even so thorough an examination, mistakes are possible.

Alcoholism and Degeneration.—Under the above title a valuable list of statistics is published by G. v.

Bunge (Virchow's Archiv, Vol. 175, No. 2), which proves that alcohol really plays an enormous rôle in bringing about degeneration of the race. This is most clearly seen in the growing inability of mothers to nurse their offspring; thus, when mother and daughter of one family were not obliged to resort to artificial food, the father was a drunkard in only 2.6 per cent., while where both were unable to nurse, a history of excessive drinking was obtained in 42.2 per cent. All cases of functional derangement owing to imperfect condition of the nipples, were ruled out. The condition is hereditary, for if the mother has lost the power, it will never be regained in that particular degeneration. Other stigmata go hand in hand with deficient nursing capacity and a pronounced disposition, toward tuberculosis, nervous diseases and psychoses is very evident. The offspring of alcoholics also suffers more frequently from carious teeth.

OBSTETRICS AND GYNECOLOGY.

Supravaginal Amputation.—Statistics are worth something, and, although they are often juggled to suit individual preferences, they, nevertheless, represent a standard of work which must be a guide by which one must estimate the gravity and dangers of all operations. Herman E. Hayd (Am. Jour. of Obstet., Jan., 1904) cites the mortality of supravaginal amputation as 5.6 per cent., while that of total extirpation in the hands of more capable surgeons, is 9.6 per cent. The work of individuals, even with the serrenœud operation, is, of course, infinitely better than these figures indicate, but it would also be so if the supravaginal operation were done and the stump were dropped back into the peritoneal cavity. The suffering of the patients is less, the period of confinement is shorter, the dangers of subsequent hernias reduced to the minimum, and a more beautiful abdominal scar results, and less danger of subsequent adhesions of the bowel and viscera to the abdominal incision, with the future possibility of operation for strangulation and obstruction, and infinitely less wear and tear and labor for the operator, assistants and nurses. The writer believes that the supravaginal amputation for necessarily operable fibroids meets nearly every indication demanded of the abdominal surgeon, and can be applied, and has been applied, to every conceivable kind of tumors, with short pedicle or long pedicle, tumors growing deep into the pelvis, or out into the broad ligaments; and with results which make it a clean and ideal piece of surgery, and is the operation of choice, excepting in those cases where drainage must be provided for, or where the cervix for various other reasons should be removed. The author has had one death in fourteen cases operated upon by the method instituted by Baer and modified occasionally after the suggestions of Kelly and other more recent operators, when some special indication seemed to exist for their employment.

Ischuria in Retroflexion of the Gravid Uterus.—In looking over the literature it is noticeable that a great many explanations are put forward to account for urinary retention in cases of backward displacements of the pregnant uterus, says Chas. B. Reed (Am. Jour. of Obstet., Feb., 1904). In this fact lies sufficient evidence that none of them entirely meets the anatomical or physiological conditions. In one case it is assumed that the presence of the displaced cervix results in a definite anatomical change in the bladder—the formation of a valve-like fold, spur or tongue on the posterior wall, which is so developed that the catheter meets with no opposition, while the outflow of urine is effectually prevented by the action of the valve (Zweifel). In looking over the various factors and possibilities it is possible to summarize as follows: (1) Retention of urine in retroflexioversion is not due to direct compression of the urethra, or neck of the bladder whereby the lumen is mechanically closed. (2) It must be regarded as a form of "pressure paralysis" due to interference with the nerves supplying the bladder in some part of their course. (3) Compression of the principal motor nerve (pelvic nerve) is the most common source of retention. The part most subject to pressure is the pelvic ganglion lying near the great cervical ganglion of the uterus, although the nerve may be affected in any other part of its course, either near its distribution to the bladder, or close to the sacral exit of the component fibers. (4) Compression of the sensory nerves, either in the course of the nerve, or peripherally (in the bladder) may also rarely produce retention. (5) Both afferent and efferent filaments may be affected simultaneously in a given case of retention, but the order is usually consecutive. (6) Pathological conditions of the pelvis and abdomen, which irritate the sensory fibers of the bladder, produce the so-called "irritable bladder." (7) Retention of urine post partum and after laparotomies for tumors is due to intra-abdominal pressure, weakness of the abdominal muscles from overdistention and the dorsal decubitus.

Inversio Uteri of Puerperal Origin.—This condition is so rare, occurring as it does once in 190,000 deliveries, that Edg. Snyers (Gaz. de Gyn., Feb. 1, 1904) thinks that it is worth while to report the following case: The patient, a primipara aged thirty years, had been in labor about twelve hours, and although the cervix was fully dilated and the head in the right occipito-anterior position, forceps were applied because the uterine pains had become ineffectual. Delivery was accomplished very readily and without any difficulty. A single voluntary movement to expel the placenta by the woman, caused a complete uterine inversion. In spite of every effort on the part of the accoucheur, it was not possible to replace the uterus behind the pubis. The hemorrhage was so profuse that the operator was forced to desist and take the necessary precaution to check the hemorrhage and to administer champagne, caffeine and normal salt solution to overcome the threatening collapse. The uterus was packed with antiseptic gauze after the placenta had been thoroughly peeled off. The child was strong and healthy. On the following day renewed attempts were made to reduce the inversion, but in vain. Sixteen days later the patient developed phlegmasia alba dolens. The question of operation presented itself, but as the woman was very anemic and her general condition so bad that it was thought best to postpone this procedure until she could become stronger, care being taken to keep the uterus as aseptic as possible. In spite of all precautions the lochia became infected and the woman developed a septicemia. Finally vaginal hysterectomy was performed in order to save the patient's life.

Suprarenal Producing Lesions of Atheroma.—Atheroma is generally considered a chronic lesion of the inner lining of the blood-vessels caused by slow intoxication. To this toxic element certain authors add another fact which is general and local hypertension. Josuè (Gaz. degli ospedali, Feb. 23, 1904) has caused atheromatous lesions of the aorta in a rabbit by injecting for several months, every other day, three drops of 1-1,000 solution of adrenalin into a vein of the ear. The alterations thus produced are considered to offer a typical appearance of calcified atheroma. In one case an atheromatous plaque was distended, constituting a fusiform aneurism, such as may frequently be seen in atheromatous individuals.

SATURDAY, APRIL 9, 1904.

BLOOD PRESSURE IN SURGICAL CASES.

In February of 1903, the Committee on Surgical Research of the Division of Surgery of the Harvard Medical School undertook to determine, "as far as the opportunities in this country will allow," the extent to which blood-pressure observations in surgical cases may be of value from a clinical point of view. The Committee was instigated to this desire by the very suggestive and original work of Crile and by the recent researches of Harvey Cushing. The end in view was to be attained by the cooperation of the surgeons of the Massachusetts General Hospital, the Boston City Hospital, and the Children's Hospital in Boston.

The results so obtained were then to be collated and digested by the Committee, with the aid of the Department of Physiology, in order that a "rigid criticism might be brought to bear upon these investigations from a scientific point of view." Such was the inception of a work, the bearing of which must appear of the greatest importance, both from a diagnostic and from a therapeutic surgical standpoint.

A year has elapsed, during which Drs. Faulkner, Stone, and Murphy, of the three hospitals above mentioned, have been busied with investigations bearing upon the problem set by the Harvard Research Committee. They have presented their detailed reports, which, together with the critique and the comment of the Committee, are embodied in the *Boston Medical and Surgical Journal* of March 10. In judging of this final statement, it is well to review the conditions which have governed the joint research, in order that one may maintain the proper attitude toward the conclusions. It would be unfair, for example, to compare the undertaking with that of the famous Hyderabad Commission on the action of anesthetics, inasmuch as the latter was composed of the most eminent specialists in England, empowered by the aid of an ample research fund to maintain a series of long and difficult experiments.

The contributions of the Boston surgeons cannot be said to have the authority of specialists in this particular field of research, nor were they enabled to make any observations other than such as are possible in the surgical wards of any large hospital. On the other hand, the volume of their combined observations, together with the fact that individual bias and interpretation have been very largely eliminated by the method of a joint report, invests their conclusions with a high degree of authority and importance.

The instruments made use of by the different surgeons were of one type, namely, the Riva-Rocci sphygmomanometer, as employed by Dr. Cushing. It is now generally recognized that this instrument affords the most perfect mechanism for the clinical registration of blood pressure, far superior, certainly, to the earlier German instruments, notably that of v. Basch. The width of the armlet is a factor of considerable importance, to which the Committee has devoted some attention. It appears that the use of a 10 cm. armlet gives readings which are far more constant and more nearly independent of the influence of the soft parts than in case of a 5 cm. band. Armlets wider than 10 cm. are more cumbersome and possess no especial advantage. The exact relation borne by the readings of the manometer in this instrument with the true intravascular pressure are, however, still largely a matter of theory. Its use has not, as yet, been controlled by a series of actual arterial manometric tracings in man, and, as the Committee remarks, the different conditions in animals are not such as to ensure accurate results. Its records, therefore, possess an empirical value which is directly proportional to the volume and the accuracy of the conjoined clinical observations.

A prerequisite to the correct interpretation of the readings is a study of the normal, the physiological, and the accidental variations. In normal individuals the mercury ordinarily registers 120 to 160 mm., but may fall as low as 100, or may reach 200. Change of position, and psychic and emotional influences produce considerable variations. Age is of importance, inasmuch as the normal readings are very much lower in children. Chronic conditions, such as tuberculosis, or such special factors as nephritis and arteriosclerosis, play a very marked rôle in the final result. All these elements must, therefore, be carefully gauged in the appreciation of any reading.

Such are the general principles which must be accepted as guiding and controlling all special research on blood pressure. Unfortunately, the *positive* outcome of its work halts with this preliminary; what should come later is lacking. It does not appear that the blood pressure affords a guide of any considerable value in determining the condition of a patient either before, during or after operation, as compared with the importance of the other ascertainable physical symptoms. The blood pressure observations "serve, as a rule, only to confirm a diagnosis already made by the physical examination of the patient;" indeed, the latter affords a far more accurate gauge of the condition, and is, at once, far more easily carried out. It appears that only in cases of cerebral compression, and then only with the utmost caution, can the blood pressure be regarded as an important element in diagnosis.

The conclusions of the Commission, disappointing as they may seem when compared with the prejudices and anticipations of the medical world on the subject of blood pressure, are to be accepted for the time being, at least, as authoritative. Nevertheless, it is quite certain that the last word has not yet been spoken upon blood pressure, and its bearing on surgical operations. The crux of the matter would appear to lie in the fact that the blood pressure is not at one time identical in all the various vessels of the body. It may be high in the extremities and low in the splanchnic area, a condition which of itself would tend to overfill the latter system, and so, by a process of "bleeding the patient into his own vessels," prove the very cause of shock. Such, perhaps, was the condition in those cases recorded by the Commission, in which "the evidence, as obtained from blood pressure observations, appeared even to be misleading." Postulated this condition, it is evident that a high peripheral pressure becomes a prognostic omen of ill import, and calls for reduction, while the splanchnic vasomotors are to be simultaneously stimulated. Be this as it may, it is certain that the matter of blood pressure is quite too complicated to be settled by the Riva-Rocci alone, and that further investigations and other means will have to be invoked before its full significance is understood or appreciated.

PATHOLOGY AND SURGERY OF THE PANCREAS.

A. W. Mayo Robson has recently delivered a series of lectures on certain diseases of the pancreas which are full of charm and instruction. Failing the privilege of hearing them, every practitioner of medicine should heed what this most brilliant English investigator has to say on this little known topic.

It is a matter of pride to Americans that he should introduce these Hunterian lectures (*British Medical Journal—Lancet,* March 19, 26, *et seq.*) by referring to the work of an American. He quotes fully and gives diagrams from Opie's monograph, which, as is well known, discussed the relations of the ducts of Wirsung and of Santorini, and the bearing which these varying anatomical structures have to the etiology of pancreatic disease.

It cannot be expected that the general practitioner should follow in detail such intricate considerations as those presented in this contribution of Robson's. The chief matter of interest and of importance centers in what he has to say concerning the symptomatology of the diseased pancreas. His profound researches have carried him to the point where he frankly states that the diagnosis of pancreatic disease is far from easy, yet he gives us a classification which can safely be used for a basis of treatment. Robson groups the symptoms and pathology, because, as he well says, they are in this organ peculiarly inseparable.

The variations from the normal he discusses first, under digestive symptoms, second under physical signs, third under metabolic symptoms, and four under symptoms artificially produced. Under digestive symptoms, he submits the following: (*a*) Steatorrhea or fatty stools; (*b*) Azotorrhea, or faulty digestion of albuminous foods: (*c*) Sialorrhea; (*d*) Diarrhea; (*e*) Dyspeptic disturbances; (*f*) Emaciation, and (*g*) Nausea and Vomiting. Physical signs: (*a*) Presence of swelling or tumor; (*b*) Fever; (*c*) Pain and tenderness with muscular resistance; (*d*) Pressure on

adjacent organs; (*e*) Hemorrhage and (*f*) Jaundice. Metabolic symptoms: (*a*) Glycosuria; (*b*) Other urinary changes. Special symptoms: (*a*) Alimentary glycosuria; (*b*) Sahli's symptoms. Each one of these subdivisions is discussed with the author's usual clearness.

Of the whole group, perhaps the most interesting is centered upon the discussion of the urinary changes. The conclusions along these lines are as follows: Glycosuria is not common and cannot be relied on as a diagnostic symptom in disease of the pancreas, but when it exists along with other signs, it is extremely serious, and, in fact, as a rule, indicates an incurable condition. In turn indicanuria, maltosuria, pentosuria, and lipuria have been advanced as of diagnostic importance in pancreatic troubles. All these have been severally advanced and endorsed as useful signs of pancreatic disease, but it is significant that the small degree of importance which is attached to them is exemplified by Osler's discussion of the subject. He says: "The condition of the urine in diseases of the pancreas has no special peculiarities."

All investigators of pancreatic disease are eagerly hoping for a verification of Mayo Robson's prophesy, made before the American Surgical Association in Baltimore, during 1901, that he would shortly be able to suggest the means of establishing positive diagnosis of certain pancreatic disorders through urinary test. At that meeting he stated his belief to be that he was then able, by the examination of certain crystals, to distinguish between acute and chronic inflammations and between simple and malignant diseases of the gland. Since that date, the test has been applied to every case that has come under the author's care in which the pancreas was suspected, and also in a large number of control cases. The technic of the method of preparing these crystals, as discussed by Cammidge, will be considered later.

A statement from so very high an authority as Robson that a test has been found which enables the surgeon with a reasonable degree of surety to differentiate between a curative, benign condition of the pancreas which calls in the most imperative manner for operative intervention, and a malignant growth of the gland, for the treatment of which operation can avail but little and is therefore virtually contraindicated, is easily seen to be a matter of the profoundest importance. If, as is cited in his paper, cases have been presented to him which, with his generally admitted unequaled powers of diagnosis of pancreatic lesions, he has found himself unable positively to differentiate and has hence felt himself unable to treat except upon the findings of the urinary analysis, how welcome will this added diagnostic power be to those surgeons of lesser experience in this matter than Robson.

Second only in interest to the discussion of the urinary findings is the author's presentation of the causes of pancreatic hemorrhage. In all he dwells upon eight causes which in his opinion are either predisposing or exciting in their influence. Vascular disease of all kinds, headed by alcoholic or syphilitic degenerations, is naturally considered the paramount factor. Trauma may be a cause. The tissues of the pancreas are soft, and although the gland is well protected, it may be bruised by a violence which seems but slight. Fatty degeneration of the gland cells and fatty deposits in the pancreas, due to whatever cause, may lead to want of suitable support to the blood vessels which are thus rendered unable to withstand the normal blood pressure. This, in the author's opinion, accounts for the hemorrhagic pancreatitis so often seen in fat and flabby individuals. Fat necrosis in the gland or its vicinity has been suggested by Balser, who has found ground in support of his views. Disintegration of neoplasms, such as cancer or sarcoma may be the cause of extensive hemorrhage. Embolism of a pancreatic artery has been reported by Molliere, as the cause of the bleeding. It is well known that many general causes, which lead to hemorrhage elsewhere, may give rise to the lesion in the pancreas. Heart and lung disease, hepatic cirrhosis, hemorrhagic diathesis, the exanthemata and various forms of poisoning may all cause pancreatic hemorrhage. Pancreatitis itself may undoubtedly lead to a hemorrhage, but it would seem probable as a rule that the effusion of blood into the organ takes place rather as a result of some of the before mentioned causes and produces the pancreatitis rather than vice versa. Large pancreatic hemorrhages are probably more common than is usually supposed.

From this discussion of the purely clinical side of pancreatic disease, one can turn profitably to a presentation of the technic of the laboratory findings as given by P. J. Cammidge, whose paper follows Mr. Robson's. In 1900, he started upon the theory that there was some connection between fat necrosis and the hemorrhagic tendency so typically observed. He therefore examined the blood of several cases for glycerin

and glycerin derivatives. He found, however, that while this might theoretically be possible, its proof was practically impossible, because of the small amount of blood obtainable. He and Robson then turned their attention to the urine, and, recognizing the selective power of the kidneys by which they detect and excrete abnormal constituents of the blood, endeavored to show that the soluble products of fat necrosis or their derivatives, might be present in sufficient bulk to make them easily demonstrable.

Since these findings probably represent the most important advance which has been made in laboratory diagnosis recently, the more or less extensive technic should be widely known. It is as follows: The specimen of urine is filtered and 10 c.c. are poured into a small flask, one c.c. of HCl is added and the mixture boiled for ten minutes. A mixture of 5 c.c. of urine and 5 c.c. of water is then poured into the flask, which is cooled. Lead carbonate is now slowly added, to the extent of four grams, and after the completion of the reaction, the urine is filtered. To the clear filtrate are now added two grams of sodium acetate and .75 grams of phenylhydrazin hydrochlorate, and the mixture is boiled for four minutes. It is then poured into a test tube and allowed to cool. In from one to twenty-four hours a yellow deposit forms which with a one-sixth objective is seen to consist of sheaves and rosettes of gold and yellow crystals. Obviously, all sugar must be removed from the specimen before this method is utilized. The crystals met with in non-pancreatic cases turn brown and dissolve in dilute sulphuric acid in a somewhat different manner than in other conditions. The difference in the shape of the crystals and the increased time taken to dissolve them in sulphuric acid is the basis upon which the differential diagnosis is made.

The correct diagnosis of malignant disease requires care, but it can be made, Cammidge says, with a very considerable positiveness. The crystals are slow to dissolve, are large and broad, but it must not be forgotten that occasionally there is associated with the malignant disease a certain amount of inflammation which interferes slightly with the positiveness of the test.

VARIOLA.

It has long been known that the staff of the Pathological Department of the Harvard Medical School, at the head of which is Prof. W. T. Councilman, has been interesting itself in variola. Now and again there have been reports and articles in the progress of the work, but these have been palpably of the nature of preliminary communications rather than of final statements, and have served to whet curiosity rather than satisfy it.

However, the time has finally come at which the fruits of these two years of labor and research have grown ripe for publication, and Drs. Councilman and Ernst have seen fit to present them in a noteworthy special number of the *Journal of Medical Research,* for February. The number comprises eleven articles and an epicrisis by Councilman. Of these articles, the most comprehensive is that which deals with the general pathological anatomy and histology of variola, the joint production of Councilman, Magrath, and Brinckerhoff, based on the study of fifty-four autopsies. The work has been done with the help of the most recent methods in histological technic, and constitutes a really important advance in many of the details which have long formed a fruitful subject of dispute. The development of the specific lesion, or pock, which presents a number of problems of considerable difficulty, has been traced with especial care.

It appears that the lesion is inaugurated by a degeneration of the cells of the lower layer of the epidermis, which is accompanied by an exudative inflammation. The products of the latter, at first predominantly serous, later more or less cellular, are contained within the spaces of a reticulum formed by the degenerated cells. With the increase of the exudate, the fibers of the reticulum eventually yield and rupture, and the typical, dell-shaped pock becomes a pustule. This process may take place wholly within the epidermis, or the corium may form the bottom of the pustule. Involution of the lesion is accomplished by absorption or evaporation of the fluid portion, exfoliation of the necrotic cellular débris, and regeneration of the epithelium. Such is the genesis and development of a lesion the nature of which has been a fruitful source of controversy ever since the early researches of Weigert. It is something characteristic and tangible in a disease which is otherwise most elusive and mysterious. Interest in the pock, however, is but a step toward the more intimate acquaintance with the etiological factors of the disease.

It has always been felt that the cutaneous lesion, presenting in its various phases a reflex of the clinical course, and apparently even determining the character of the latter, would eventually afford an explanation of much that has hith-

erto been inexplicable. The serious study of the pock from this standpoint is of rather recent date inasmuch as it had to wait upon an improvement in histological technic and the development of the bacteriological methods. It cannot be said, however, that the researches of the last twelve years have gone very far in clearing up the mystery. Bacteriological investigation has served to show quite definitely that none of the bacteria play anything except an accessory rôle, purely secondary in character, in the development of the pock and of the disease. In so far, their work has been of positive value.

Further than this, there is little but confusion and contradiction in the literature. In 1892 Guarnieri described a certain protozoan organism contained within the cells of the pock, and varying in size from that of a micrococcus to a nucleus. This work has been the point of departure of a large number of special researches with the aid of the most exact and delicate methods; unfortunately the results have not been commensurate. While a goodly number of observers have confirmed the findings of Guarnieri, there have not been wanting as many who have absolutely contradicted his results. In view of these conditions, skepticism has been the only attitude possible upon the etiology of smallpox. It has been the great service of Councilman and those associated in his work to put the discovery of Guarnieri upon a fairly firm foundation, and to have added to it many details of considerable value. They have found not only that the cells contain a microorganism which is peculiar, and which may be shown to be inoculable and transmissible, but they have succeeded in tracing and determining at least a part of its cycle of development. The latter part of the work has been assigned, very properly, to a specialist in protozoan zoology, Dr. G. N. Calkins, of Columbia College. Dr. Calkins accepts the name given by Guarnieri of *Cytorrhyctes variolæ*, and assigns the organism to the subclass *Neosporidia*, of the sporozoa; it belongs to a family (*Cytorrhyctidæ*) of which only two other representatives are known to exist, the parasite of the macronucleus of *Paramoecium*, and the brook trout parasite. The organism presents two phases of a life-cycle, a cytoplasmic, which is the earlier, and an intranuclear. The organism invades the epithelium as a minute homogeneous gemmule. This undergoes growth and differentiation, and by a schizogenetic process gives rise to a large number of other gemmules. After a further course of development, certain of these bodies find their way into the nucleus, where they undergo a differentiation which has been interpreted in the light of a sexual specialization. Thus it is believed that the sexual phenomena, including conjugation and subsequent division, are a characteristic of the intranuclear phase of the cycle. The gemmule, however, is the beginning and end of the entire process.

Such, in brief, are the chief elements in the parasitology of variola, and it is not easy to praise too highly the character of research to which they owe their elucidation. That a seal has been put upon the problem it would be presumptuous to believe. There still remain a host of questions to be answered, the unraveling of which will certainly be even more difficult and laborious than were the steps which led to the discovery of the parasite. The fate of the gemmule after it leaves the body, the transportation of the infecting agent by the body fluids, the method of cellular invasion—all these are questions of prime importance which urgently demand investigation.

Meanwhile, the assistants of Councilman have gone further to establish by means of experimental researches the constant and etiological association of the parasite and the lesion. It would be impossible to summarize all their work, for the details of which the original articles must be consulted. Suffice it to say that the combined researches, which really form integral parts of one larger idea, lead almost irresistibly to the conclusion that the real cause of the disease has finally been determined that it appears both in variola and vaccinia, and that the differences in character between these two manifestations are due entirely to modification in the life-cycle of the organism.

ECHOES AND NEWS.

NEW YORK.

Mount Sinai Hospital Appointments.—The first two positions on the House Staff were given to Ernest Sachs and Orville Schell who are to be graduated in June from the Johns Hopkins Medical School. The eighth place was given to Eben Alexander, Jr., of the Jefferson Medical College, Philadelphia. The intervening positions were assigned to members of the graduating class of the College of Physician and Surgeons, whose names were published in the last issue of the Medical News.

Hospital Interneships.—The following men from the College of Physicians and Surgeons secured hospital appointments during the past week: St. Mark's Hospital, E. J. Leavitt. German Hospital of New York, first, M. J. Myres; second, F. E. Neef; third, L. Fichter; fourth, T. J. Shreck; alternates, W. F. Bopp, H. E. Kudlich. Post-Graduate Hospital, L. P. Runyon, T. O. Vanamee, E. J. Smith. Newark

(N. J.) City Hospital, C. R. O'Crowley; alternate, J. Levy. St. Vincent's Hospital, M. S. Black, A. M. Bell, D. C. Fassett, D. J. Flynn, W. J. O'Leary, T. J. Cherry. Norwegian Hospital (Brooklyn), Charles Eastmond. Presbyterian Hospital, R. W. Cook, D. Cook, St. John Ward. H. H. Mason, Geo. Lathrop; alternates, B. W. Paddock, A. Vander Veer, Jr. St. Luke's Hospital, W. Ward, F. V. Hussey, A. R. Moffitt, D. G. Littell, S. M. Chessman, A. D. Mittendorff; alternates, G. Hale and I. O. Woodruff.

Gift for Eye and Ear Infirmary.—Mrs. John E. Parsons, of 30 East Thirty-sixth Street, daughter of the late Benjamin H. Field, ex-President of the New York Eye and Ear Infirmary, has sent $1,000 to Treasurer John L. Riker of the Board of Directors of the infirmary to go toward a fund to be used for the perpetual endowment of the institution.

Gift to German Hospital.—The will of Maximilian Schaefer, who died about two weeks ago, has been admitted to probate in this State, and provides for the distribution of $12,000 among various charities. Of this amount $7,500 is bequeathed to the German Hospital at Lexington Avenue and Seventy-eighth Street. Mr. Schaefer in the will directs that of the bequest to this hospital $5,000 be used to endow a bed for the free treatment of employees of the F. & M. Schaefer Brewing Company and such other patients as may be designated from time to time by the executors and trustees.

Plans for Convalescent Hospital.—New York's first convalescent hospital is to be established at New Dorp, Staten Island, by St. John's Guild. This will inaugurate a system of hospitals for this city similar to those of London, which have accommodations for more than 13,000 convalescents. That New York has never had more than 200 beds in all its hospitals for this class of patients has long been deplored by physicians, who are in a position to know the vital need of special care for recovering invalids. Twenty-five thousand dollars will be expended at once to equip the summer Seaside Hospital at New Dorp for winter use, and plans for a $350,000 addition are being considered by the guild. Dr. William Maynard has recently returned from a long sojourn in London, studying the convalescent hospital system there for the St. John's Guild. His plans for the installation of the first convalescent hospital in the city were formally approved at the meeting of the trustees of the guild on Tuesday night. Three hundred and twenty patients will be accommodated by the first expenditure. Many hundreds more are to be provided for later.

Sensible Comment.—A doctor in an Illinois town was recently quoted as contributing to a discussion as to whether the newspapers should publish the name of the attending physician in an accident case, the statement that to have this done "would spur him on to greater efforts to secure the complete recovery of his patient." That is truly a curious remark, however one looks at it, and curious, too, is the way the New York *Medical Journal* looks at it. "We always hesitate," it says, "to comment on newspaper quotations of the alleged statements of physicians," which is a nice, pleasant way of beginning, rather characteristic of the medical press, and then it continues as follows: "If any member of our profession made the foregoing remark he should instantly matriculate into some profession or business where the lack of journalistic comment, which is so stimulating to him, would not necessarily imperil the lives of others. The remarks exhibit a mental attitude that we cannot harmonize with our concept of any physician, however unfit." Of course that's all right in substance, but its implication that good doctors either are or ought to be indifferent to "journalistic comment" is just about as absurd as was the Illinois doctor's implication that he would work harder for a patient with whom the newspapers had connected his name than for one whom he could cure—or not cure—without attracting any particular attention. That doctors can make improper use of publicity is known to none better than the men on newspapers, one of whose constant duties it is to see that the doctors who want to do just that thing do not succeed too often in doing it. There are, however, proper as well as improper uses of publicity, even for a doctor, and even in medical matters there not a few lay papers that compare with the medical press about as the ordinary physician compares with the specialist. The trouble with the doctors is that they are always regretting the days when they were a sort of priesthood and their art was a "mystery" understood only by themselves—and by themselves none too well. There's no mystery about it now, and the pretense that a layman necessarily is incompetent to criticize the language or the acts of the doctors is the wildest nonsense.

The otherwise sensible comment of the *Times* is spoiled by this silly ending.

New York University Building Decision.—By a recent decision of the Court of Appeals the final step has been taken toward the settlement of the controversy between the N. Y. University and its former Medical Faculty, the members of which resigned in 1898 and founded the Cornell University Medical College. The Court of Appeals confirms the decision of the lower courts ordering the return of the building and property to the former owners. The University Medical College like all others of its time was originally and for many years a proprietary institution holding its charter through the N. Y. University, but wholly independent of it in management. In the effort to improve standards of teaching it became evident that this proprietary quality should be eliminated, and the Faculty accomplished this by the aid of a gift of money from Col. Payne by which the ownership of the Faculty was cancelled and the property was placed in the hands of a corporation fund for this purpose, the Faculty agreeing to accept fixed salaries in lieu of a division of the profits. After a few years, with the intention of establishing a closer connection with the N. Y. University, it was agreed that the corporation which held the property and managed the affairs of the College, composed largely of members of the Faculty, should transfer their property and function to the N. Y. University, and that the latter should manage the College through a "Medical Committee" of the Council composed of three members who should be satisfactory to the Faculty. On nomination of the Faculty two new members were elected to the Council, and, with Col. Payne, the donor of the money, constituted this committee. Within a few months disagreements arose over a proposed consolidation with Bellevue Hospital Medical College; the recommendations of the Medical Committee were overridden by the Council, and the Faculty held that the agreement had been broken. Reestablishment of the original status was refused by the Council of the University, and a year later the Faculty seceded and established the Cornell University Medical College, and the Corporation which had transferred the property sued for its return. The N. Y. University then took over the Bellevue Hospital Medical College as its medical school with most of the Faculty and made it its medical department. The property is valued at $150,-

000. The results of this final decision are that the large buildings formerly occupied by the New York University adjoining the Loomis Laboratory are now the undisputed property of the Corporation, many of whom are members of the Faculty of the Cornell University Medical College.

PHILADELPHIA.

Frankford Hospital.—Dr. H. E. McCaffrey has assumed the duties of resident physician in the Frankford Hospital, succeeding Dr. J. W. Kenney, who recently resigned. Dr. McCaffrey comes from Bristol, R. I., where he was for some time in charge of a sanitarium.

Changes in Bureau of Health.—Drs. J. S. McClintock and Mary E. Pennington began on April 1 their duties as bacteriologists in the Bureau of Health, succeeding other employees whose resignation had been asked. Chief Milk Inspector Byrnes, associated with the Health Department for more than twenty-five years, has been superseded by former Assistant Inspector Clegg.

Many Trips for Ship's Surgeon.—When the Red Star Line steamship Switzerland docked here during the past week, her surgeon, Dr. Edmund Y. Burrows, completed his two hundred and fiftieth round trip between this port and Europe. This record is claimed to be unequaled. Dr. Burrows has spent nearly all his life on the seas, having been a seaman aboard various ships before his appointment to the Switzerland.

Medical Inspection of Schools Instituted.—The daily medical inspection of children in the public schools of Philadelphia began on April 5. With the possible exception of a few schools in outlying sections, every school will be visited daily. Director Martin states that the first object of the inspectors will be to exclude children suffering from contagious diseases; secondly, to exclude all those who have non-contagious diseases, but who are too ill to remain in school. Afterward there will be made a careful examination in order to discover physical defects, including spinal curvature, flatfoot, deafness, defective eyesight, narrow chest, etc. Diagnoses will be communicated to teachers by a code in order that the child may not know the nature of the disease. In all cases the parents are to decide regarding any medical care to be instituted.

Millions for Improvement of Hospitals.—Commissions for new buildings and improvements on various hospitals in the city, now in the hands of builders, amount to several millions of dollars. Among the institutions thus extending are the Jefferson, St. Agnes, Episcopal, Will's Eye, Presbyterian, Home for Incurables, Rush, University, St. Timothy's, Methodist, Howard, Mt. Sinai, and the Phipps Institute. At the Home for Incurables at Forty-eighth Street and Woodland Avenue the first of two cancer wards is to be built.

Course in Tropical Medicine.—A course of ten lectures on Tropical Medicine has been instituted by the Medical Department of the University of Pennsylvania. The present year's course is being delivered by Major Guy L. Edie, U. S. A. They began on March 23 and will continue on each Wednesday and Friday until completed. They are given in the Laboratory of Hygiene, from 5.30 to 6.30 P.M. Members of the profession are cordially invited to attend.

Director Martin to Establish Fresh Air Retreat.—Dr. Edward Martin, Director of Public Health and Charities, has purchased an old mansion and twenty acres of land near his summer home in Delaware County and will transform it into a fresh air retreat for sick and needy children who seldom see trees or grass. In order to get them out doors as much as possible, tents will be supplied in addition to the house itself. The home will be supplied with occupants from those children coming under the personal notice of Dr. Martin and also to some extent by various societies. The place will be ready for occupancy about May 1. It is entirely a private undertaking, one that Dr. Martin has had in mind for several years.

Massage of the Heart as an Aid to Resuscitation.—At the meeting of the Philadelphia County Medical Society held March 23, Dr. W. W. Keen reported two cases of massage of the heart as an aid in resuscitating patients under the influence of anesthetics. One was a personal case of laryngectomy in a patient who took the anesthetic very badly, both at that time and during a previous operation. Other methods of restoration having failed, the abdomen was opened and the heart massaged through the diaphragm without opening that structure. This manipulation was unsuccessful in reviving the patient. The second case was one of hysterectomy, reported through the courtesy of a Swedish physician. In that instance the chest wall was resected and the pericardium laid bare. Recovery occurred. Dr. Keen also reviewed 25 additional cases from the literature. He believes the measure to be justified in certain instances after the apparent failure of other less radical means; other methods, even when massage is employed, must not be neglected. In answer to a question, Dr. Keen said that the determination of time under such circumstances was always a very difficult matter, but broadly speaking, he would not resort to massage under five minutes after pulsation ceased, and would not use it after ten had elapsed.

Vaccination Law Needed.—Dr. Benjamin Lee, Secretary of the State Board of Health, looks upon the power to enforce vaccination during the outbreaks of smallpox as among the most valuable of the legislative means of controlling the disease and would welcome such power in Philadelphia. West of the Alleghanies the epidemic appears to be under control and this is attributed by Dr. Lee largely to the power of compelling vaccination vested in the health boards of cities of the second and third classes. In Pittsburg and Allegheny this procedure has diminished the number of cases fifty per cent. during the past three months. In the Eastern parts of the state there is great difficulty in convincing the physicians of some counties that smallpox actually exists; some pronounce the disease to be an entirely new one, never before described. The State Board of Health is now furnishing vaccine virus free to small villages and rural districts and bearing at least part of the expense of vaccination.

Marked Increase in Typhoid.—For the week ending April 2 there were reported 321 new cases of typhoid fever, the largest number for many years. Deaths for the same period numbered 24. Since January 1 there have been 2,056 cases of the disease. Thorough investigation of the milk supply of the city has eliminated that source of infection and the water supply is held responsible.

War on Baby Farms.—Coroner Dugan is at present conducting an investigation into several infanticide cases and numerous arrests have been made. An important case is now under trial. Revolting details regarding the doings of malpractitioners and

the keepers of "farms" have come to light. Among these were the burning in furnaces of live infants. Evidence of a combination of these "doctors," extending into cities other than Philadelphia, is said to have come to light. As one result of the commendable investigation now being made, the proprietors of at least a dozen suspected places have closed their establishments and left the city. More disclosures are yet to be made.

Phipps Institute.—It is announced that Dr. M. P. Ravenel, of the Medical staff, will shortly sail for Genoa, Italy, to spend the greater part of the summer with Professor Edoardo Maragliano in the study of the question of specific therapy of tuberculosis and a possible vaccination against that disease. The Phipps Institute has already accomplished much in the cure and prevention of tuberculosis and valuable results may confidently be expected from this latest enterprise of the institution. The ability of Dr. Ravenel as a conservative scientific investigator is recognized by the profession throughout the world.

Dr. McLeod Able to Walk.—Dr. George I. McLeod, of Ardmore, who had both feet amputated, as the result of being crushed by a train last December, is now, by the aid of artificial feet, able to walk with but a slight limp. This happy outcome of a most severe injury is a source of great delight to the many friends of Dr. McLeod. He is soon to resume the practice of his profession.

CHICAGO.

Personnel of Examining Board.—The County Civil Service Commission has announced the members of the examining board for the promotive examination for the work of senior physicians at the Dunning institutions as follows: Nervous and Mental Diseases—Drs. Sydney Kuh, Hugh T. Patrick, and Daniel R. Brower. Medicine and Surgery—Drs. Frank Billings, John B. Murphy and L. E. Schmidt. Tuberculosis—Drs. Wm. A. Evans, Geo. W. Webster, and A. C. Klebs. The examination will take place at the Dunning institutions April 14, 15 and 16.

Dunning Staff.—The County Board has confirmed President Foreman's appointments to the consulting staff of the Dunning institution. Following are the appointments: Dr. Frank Billings, consulting physician (internal medicine); Dr. John B. Murphy, consulting surgeon; Dr. Wm. A. Evans, consulting pathologist; Dr. Hugh T. Patrick, consulting physician (insanity); Dr. Arnold C. Klebs, consulting physician (tuberculosis).

Caution Against Hydrophobia.—This subject is discussed at considerable length in the weekly bulletin of the Health Department, and among other things the report says: "The number of rabid dogs which have been killed during the last few weeks, brings from the department of health the advice that the public should appreciate the importance of securing a dog that has bitten anyone and keeping him alive until it is positively known whether or not he is suffering from rabies." It also recapitulates the symptoms of rabies in dogs as follows: "Beware of a dog when it becomes dull and hides away; appears restless; always on the move and prowling; whose countenance is somber and sullen; walks with head down like a bear. Beware of one that barks at nothing, when all around is still. Beware of a dog that scrapes incessantly and tears up things. Look out for the dog who has become too fond of you and is continually trying to lick your hands and face. Beware, above all, of the dog which has difficulty in swallowing, which appears to have a bone in its throat, and one that has wandered from home and returns covered with dirt, exhausted and miserable."

Meeting of Bellevue Alumni.—On April 11 the Fourth Annual Meeting and Dinner of the Western Alumni Association of the University and Bellevue Hospital Medical College will be held at the Sherman House. The guests on this occasion will be Drs. Joseph D. Bryant and Egbert Le Fevre, of New York. The officers of the Association are Dr. David W. Graham, President; and Dr. Willis O. Nance, Secretary.

Drainage Canal.—The value, as a health protection, of the drainage canal, incomplete though it is, was strikingly manifested during the week, according to the Health Department. The waters of the streams about Chicago, formerly tributary to the river and thence to the lake, were higher even than in the record year 1892, in which year there were 1,489 deaths from typhoid fever, and Chicago's death rate was the highest of any city in the world. In that year the vilely polluted contents of the main river and its branches were poured incontinently into the lake without control. A volume of from 600,000 to 700,000 cubic feet per minute has been poured steadily through the drainage channel away from the lake down the Desplaines Valley. If 1904 escapes the typhoid tragedy of 1892, it will be due solely to the agency of the incomplete main drainage channel.

Intelligent Care of Infants in Summer.—Dr. A. Belcham Keyes recently gave a talk on this subject before the School of Domestic Arts and Science, Chicago, and after giving some sensible advice and timely hints to mothers, he spoke of the work of the Milk Commission, saying that under the auspices of the Children's Hospital Society of Chicago, its work is to inspect farms; to advise with the farmer as to the improved methods of hygiene for the cow, cleanliness in milking and shipping the milk to the whole city of Chicago; also to distribute good, pure milk, fresh, or Pasteurized, or modified, to the poor mother at a reduced price; also to instruct the mother, at mothers' meetings, in hygiene and feeding. This good work was done last summer to the extent of distributing among the poor 222,000 bottles, representing nearly 51,000 quarts of milk, besides a large quantity of barley water. The benefit of this work was not to the poor alone, but to every householder in Chicago. Its inception was in the visit of a leading Austrian specialist in deformities, who called attention to the long-felt needs of children for proper care in sickness, as well as for a preventive or prophylactic care of their hygiene and diet in infancy. Dr. Keyes reviewed what good feeding in infancy prevents: Firstly, it lessens the number of cases and mortality from acute intestinal and infectious diseases. Secondly, it avoids the distressing conditions known as English disease, or rickets, from which a large number of children die yearly, and, if they survive the disease, are often deformed for life. Thirdly, a large number of the cases of tuberculosis, especially of the bone in young children, are predisposed to the disease by the catarrhal conditions of the intestines, in which condition they take into the circulation the bacillus of tuberculosis, which the imperfect inner lining of the blood vessels of the long bone make a good resting place, with its resultant chronic invalidism and later frequent implication of the lungs and death. Fourthly, proper infant feeding—even if these first

three are escaped—is a necessity for the good health and, perhaps, even the formation of the character of the child that later will become the man, and this is the preservation of the health and character of the American-born man.

CANADA.

No Adulteration in Canadian Liquors.—Under date, Ottawa, March 31, the Department of Inland Revenue have issued a bulletin on distilled liquor. The samples analyzed consisted of: Rye whisky, 91; white, 30; Scotch, 24; Irish, 2; gin, 27; rum, 12; brandy, 30; total, 216. Mr. McGill, who made the analysis, states: "No delcterious substances have been found in any of these samples. In accordance with special instructions, I have made examination for alkaloids in all whisky samples, having less than 75 per cent. proof strength. A negative result was obtained in every case. The principal adulterant is water. In order to enable me to say, whether or not a sample may be styled adulterated from dilution with water, it is necessary to recognize some standard strength for alcohol. The British Sale of Food Amendment Act for 1879, fixed the minimum limit strength for gin at 65 per cent. and that for brandy, rum and whisky at 75 per cent. proof spirit. Although these limits are not legally recognized in Canada, I have used them (in the absence of any other standard) for purposes of comparison. The spirits most tampered with are whisky (rye and malt) and gin, while gin shows a noteworthy falling off in strength." In conclusion Mr. McGill says: "I may add that the furfurol test and the production of a distinct turbidity (opalescence) on the addition of water to the distillate are the chief means we possess for discriminating between a liquor which has been produced by direct distillation from the 'mash' and one which has been manufactured by reducing rectified spirit with water to the desired strength and further addition of flavoring or coloring matter. Scotch and Irish whiskies and gin, rum and brandy are liquors of the first type (sometimes spoken of as pot-still spirits). Rye whisky and white whisky (malt whisky) are usually manufactured from rectified spirit."

The Donations to McGill University.—Sir William McDonald's recent very handsome gift to the Student's Union is a further reminder of the extent to which McGill is indebted to Montreal citizens. The list of benefactions to McGill University is a long one. In addition to the large gifts of such men as the Hon. James McGill, Sir William McDonald, Peter Redpath, Esq., Lord Strathcona, the Molsons, etc., there have been a large number of substantial donations, which have not excited quite as much comment in the public press, but which have nevertheless been of much service to the University and the cause for which it stands. The total donations in lands, buildings, apparatus, together with the Hon. James McGill's original endowment and donation in land reaches the value of $2,300,172.72. Miscellaneous endowments reach the sum of $2,074,504.78, while special chairs have privately been endowed to the value of $962,393.32. A sum amounting to $60,790.80 has been contributed to a fund for establishing scholarships, granting medals, etc. The total amount in donations of lands, endowments, etc., reaches in sum total the very handsome figure of $5,597,861.62.

The Medical Branch of the Canadian Militia.—The Medical Branch of the Militia Department has now on order a large supply of material and equipment that will add materially to the efficiency of this service, and when certain reforms now in contemplation are carried into effect, will make it one of the best branches of our citizen army. The purchases include 18 ambulance wagons of a new type designed by Lieutenant-colonel Fiset, Director-General of the Canadian Army Medical Service. Each wagon will be a hospital in itself, with room in it for four patients lying down, or 13 sitting. There will be beside nine water carts, that is, one for each bearer company; 12 sets of medical panniers, 12 sets of surgical panniers, 18 sets of santeen panniers, 50 surgical haversacks, and 50 monkey boxes. Part of this material is being manufactured in Ottawa, while the balance is being brought from the old country.

Ontario Doctors May Be Prosecuted for Failure to Make Returns.—Dr. Hodgetts, Secretary of the Ontario Board of Health states that in future the medical men must report all cases of infectious or contagious diseases. He has looked up the records and finds that in 1902 there were returned to the Department 1,542 cases of typhoid fever, while the hospital statistics show 2,067 cases, with 242 deaths. In 1903 a return from the 700 divisions showed 1,012 cases, while in the hospitals there were 1,918, with 298 deaths. The purpose of the Medical Act, he says, is being destroyed and the healthy condition of the province very much endangered. During the past few months several outbreaks of typhoid fever have been covered up by medical men failing to report. Prosecution may be resorted to in order to wake doctors up and protect the public.

Canadian Medical Men for Europe.—Dr. J. Alex. Hutchison and Dr. George E. Armstrong, of Montreal, along with Dr. Murray McLaren, of St. John, N. B., and Dr. W. G. Anglin, of Kingston, Ont., the latter of whom has just recovered after a prolonged attack of blood poisoning, will sail on April 9 from Boston, for Italy. They will visit the principal hospitals of that country, finally making their way to Vienna. They will visit the home and hospital of Dr. Lorenz.

Legal Action Re Adulteration of Foods.—The Medical Health Officer of Montreal, Dr. Laberge, has taken two important actions in the Recorder's Court against an American and a Canadian firm that were selling canned tomatoes in Montreal that were colored with aniline. The importance of the actions was that they were being taken under the Federal Act, which gave the city power to prosecute for fraud, while under the Provincial Act, they can only prosecute on the plea that such coloring is dangerous to health. It will be the first time that the city has taken procedure under the Federal Act, and where fraud will be charged.

New Brunswick Provincial Hospital for Cure of Nervous Diseases.—The New Brunswick legislature has before it a bill to change the name of the Provincial Lunatic Asylum to the New Brunswick Provincial Hospital for the Cure of Nervous Diseases. The bill authorizes the commissioners to employ two disinterested and competent medical men, who with the superintendent, shall examine all patients and see who ought to be in the asylum and who should be sent elsewhere. There is an impression abroad in New Brunswick that the institution has been used for the purpose of getting clear of undesirable people, who should be cared for by their friends or sent to the almshouse. It is also proposed that even where a certificate of insanity has been granted by two physicians, the superintendent need not admit the patient if he has a doubt, but may consult with an outside physician in regard to the case.

GENERAL.

Officers American Association of Pathologists and Bacteriologists for the Ensuing Year.—President, Dr. Simon Flexner; Vice-President, Dr. James Ewing; Secretary, Dr. H. C. Ernst; Treasurer, Herbert N. Williams; New Member of the council for vacancy occurring in 1905, Dr. W. T. Howard; Mem-

ber of the Executive Committee for the Congress, Dr. H. C. Ernst.

Japanese Biologists.—The *Times* speaks with approval of the splendid work done by various Japanese scientists during the past decade as follows:

"It is probably not generally known that during recent years Japanese contributions to science have been numerous and important. The most conspicuous successes of its original investigators appear to have been in the field of biological research, a study demanding great patience, manual dexterity, and a refinement of technic which are quite characteristic of the people who are now occupying so large a share of the world's notice. In their contributions to our knowledge of pathogenic microorganisms the Japanese are pushing German and French experimenters for the first place, and are far ahead of those of Great Britain or the United States. Several years ago Kitasato segregated and described the specific germ of tetanus and was admittedly the first to do so. This discovery was followed by the preparation of a tetanus antitoxin which has been extremely useful. Another Japanese, Shiga, has discovered the bacillus which is chiefly responsible for dysentery, so fatal to the soldier in war time, and use of this knowledge is being made to safeguard the Japanese troops in Manchuria and Korea with excellent effect. The absence of ameba in many cases of dysentery critically examined was the cause of much confusion in the clinical study of this disease until Shiga established the fact that in such cases the disease is due to the presence of a microscopic plant now known as the *Bacillus dysenteriæ*. Still other contributions of great value to biological knowledge have come from Japan, and the fact is of especial interest as showing in what directions the peculiar civilization of that country has developed since its association with the Western world was resumed."

A Useful Call Down.—We quote from a recent number of the *Critic and Guide*, wherein attention is called to certain statements made by the manufacturers of a new iron albuminate compound. The editor comments as follows: "1. The manufacturers state that (——) is neutral in reaction. I would ask my readers to test it with litmus paper or with phenolphthalein. I find it distinctly acid, and I think I am able to test for a reaction. 2. The percentage of iron in (——) is rather a mooted point, which I should like to get some light on. The manufacturers say: 'Each tablespoonful of (——) is equivalent to one grain of elementary iron.' Well and good. But Dr. Coblentz says: 'I find eight per cent. of iron (calculated as metallic iron) present in the state of organic combination.' This of course leads one to believe that the preparation contains eight per cent. of metallic iron, which would be equivalent to at least 19.2 grains per tablespoonful. There is a great difference between 19.2 and 1. But let us assume that Dr. Coblentz really meant to say that the preparation contained eight per cent. of the organic combination. The formula given by the manufacturers is $C_{47}N_{17}SH_5Fe_8O_{22}$. The percentage of elementary iron contained in this 'definite' chemical must therefore be $^{448}/_{1638}$ or 27.3 —%. Eight per cent. of this is 2.184, which would give us at least 5.2416 grains of elementary or metallic iron to the tablespoonful. The manufacturers themselves claim that their preparation contains only one grain of elementary iron to the tablespoonful. How to explain this discrepancy? Dr. Coblentz is a careful analyst. Is it possible that the manufacturers themselves do not know the true percentage composition of their preparation? This is not very likely. So how to explain the discrepancy? I shall await the explanation with impatience. 3. The manufacturers state that (——) is absolutely unchanged by hydrochloric acid. This statement, I regret to say, is contrary to the facts, and I am at a loss to understand how intelligent manufacturers could make such a statement. That it is very decidedly changed by hydrochloric acid will be seen from the following simple experiment: On adding potassium ferrocyanide to (——) no change is noticed. But if we add hydrochloric acid to (——) and then add potassium ferrocyanide, we get a very decided reaction; namely, we get the well-known color and precipitate of Prussian blue, which proves conclusively that hydrochloric acid does decompose (——), changing it into inorganic iron. The further statement: 'hence it is free from local action on the gastric mucous membrane,' is therefore also untrue. 4. The manufacturers state that their preparation has attracted much attention in scientific circles in Europe. I may be pardoned if I doubt the correctness of this statement. If it had attracted attention, the attention was not sufficiently strong to bring it into the medical press. Disregarding false modesty, I will state that I am probably as familiar with foreign medical literature as any one man can be. I go through every medical journal of any importance in six different languages. My memory is also pretty good—and still I cannot recollect having seen any article in the foreign literature on (——). Of course, there is a possibility of an oversight. If this is the case, will the manufacturers kindly send me the foreign bibliography on (——)? 5. One word about the American literature on (——). I shall not say that it has all been made to order, but I would ask our readers to compare Professor (——) article with the advertising matter sent out by the manufacturers. If ever there appeared a 'write-up,' this is one—or I have lost my ability to recognize and diagnose 'write-ups' when I see them. Even the phraseology is strikingly alike in some places. Is it merely a coincidence? The manufacturers of (——) will greatly oblige the medical profession by shedding some light on the obscure points which I have touched upon in this editorial." More critical comment of this kind would bring to light a number of high priced "Professors" whose write-ups have no justification.

Suggestive Vital Statistics.—The annual report of the Board of Health of Connecticut, its immediate returns covering the year 1903 and its larger tabulations ending with the year 1902, contains some very significant figures of mortality, showing the mutations of disease and the causes. One of the most striking tables shows the steady and rapid decrease of consumption in the State. The table covers a period of twenty years, during which, notwithstanding an increase of population from 622,700 to 908,420 by the nearest censuses, the annual deaths from consumption fell from 1,505 to 1,356. Based on the Board's estimate of population, the death rate per 10,000 of population fell during the two decades from 23.2 to 14.9, or a reduction of 38.8 per cent. A fact brought out is that during the first of the two decades the deaths of females from consumption was much in excess of males, while, in the last decade, over 700 more males than females died from the disease. The change is probably accounted for in part by the shifting of occupations, and in part by the fact that young women of the Irish race, who were peculiarly susceptible to consumption in New England, have become inured to the climate. As the Board of Health reports are much more complete than they were twenty years ago, the reduced mortality from consumption is, in fact, considerably greater than the comparative returns indicate. In its report for 1899 the Board showed that mortality from consumption was considerably greater in both Massachusetts and Rhode Island than in Connecticut, though decreasing rapidly in all three States. The Board approves the treatment of incipient cases of con-

sumption by the open air and "tent" plan. For this purpose a sanatorium with 250 acres is to be opened in the town of Wallingford, for which an unknown donor has given $40,000, to which gifts of $3,000 and $5,000 have been added, and another large gift is expected. As distinguished from consumption, pneumonia shows a rapid increase, and now leads all diseases in mortality. In 1903 there were 1,428 deaths from pneumonia, as compared with 1,317 from consumption. For five years before 1890, and just before the first appearance of "La Grippe," the average number of deaths from pneumonia was only 970. Heart disease shows a similar, though less marked, tendency to increase. The decrease of typhoid fever as the result of systematic efforts to locate and stamp out the source of the disease shows very impressively in the returns. In thirty-eight years the deaths per 100,000 of population fall from 109 to 22, notwithstanding fuller returns in the later years. Partly as the result of intelligent treatment of smallpox, there was in 1903 only one death in 287 cases, the disease, however, being of a very mild type. The board criticises severely the common tendency to treat measles and whooping cough as "trivial" diseases in the face of returns for 1903, which show 450 deaths from them, as compared with 439 from scarlet fever, diphtheria and croup combined. The birth returns continue to indicate the slow but steady extinction of the purely native race, births from American parents falling in ten years from 8,487 to 8,283, while births from foreign and mixed parentage rise during the same time from 11,467 to 12,576. In a considerable number of the smaller farm towns the births from foreign or mixed parentage exceed the native births, suggesting the extent to which foreigners are taking up the farms in the back country towns. In one town, for example, almost purely a farm town, the births from native parentage in 1902 were 8 as compared with 16 of foreign or mixed parentage.—*Evening Post.*

Bubonic Plague Progressing.—A dispatch from Bombay dated March 29 states that the latest available bubonic plague returns for the whole of India for the week ended March 19, show a mortality of 40,527, an increase of 7,000 over those of the preceding week. In the Punjab and the northwest provinces each there is a death rate of 10,000 weekly; in the Bombay Presidency the deaths number 8,500, and in Bengal 5,000.

$500,000 Donated to Johns Hopkins Hospital to Offset Loss by Baltimore Fire.—John D. Rockefeller has given this amount to the Johns Hopkins Hospital. The gift is to prevent the curtailment of the usefulness of the hospital by the losses caused by the big fire. The money is given outright and will be turned over to the trustees of the hospital in whatever form they may elect.

OBITUARY.

Prof. A. B. Arnold, the author of several surgical treatises and a distinguished classical scholar and translator of old Hebrew and Arabic writings, died at San Francisco last week, aged eighty-five years. He was born in Germany in 1819.

Dr. Washington H. Baker died at his home, 1610 Summer Street, Philadelphia, April 1, aged fifty-two years. He was a graduate of Lehigh and the University of Pennsylvania. He served as resident to the German Hospital, was visiting physician at St. Joseph's Hospital, and a surgeon in the Second Regiment, N. G. P.

Dr. George H. Hammond died at his home in Freeport, L. I., March 29, of pneumonia and pleurisy, aged fifty-eight years. He was the son of the Rev. Mowbray S. Hammond and for some years was a staff surgeon in the Nassau Hospital at Mineola. He was a prominent member of the Masonic and several other fraternal orders.

Dr. Stephen P. Truax, a well-known Brooklyn physician, while engaged in performing an operation on a woman in the Bushwick Central Hospital, in Brooklyn, last Thursday morning, was taken ill suddenly and died in a few minutes. Dr. Truax lived at 257A Madison Street, and was forty-eight years old. He was born in Owego. In 1891 he was graduated from the Long Island College Hospital. He was the visiting gynecologist of the Bushwick Central and a lecturer on obstetrics and gynecology in the Post-Graduate Hospital in this borough. He had been a sufferer from heart disease and had lately been afflicted with the grip. Dr. Truax belonged to the Kings County Medical Society and several Masonic organizations.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 19.

THE LATE DUKE OF CAMBRIDGE AND THE DOCTORS—THE ENDOWMENT OF MEDICAL EDUCATION.

The Duke of Cambridge, a near relative of King Edward VII., has just passed away at the age of eighty-five years. He was for forty years Commander-in-Chief of the British Army, and had at any rate one quality which proverbially belongs to the British soldier: he stuck to his post and seemed determined to die there with his drawn salary in his hand. But circumstances were too much for him and he had to resign a few years ago, much against his will. It could not be said of him that he never set a squadron in the field, for he was in charge of a division in the Crimea where he showed himself so little master of his trade that had not Colin Campbell, afterward Lord Clive, been at his elbow, the force under his command would have been destroyed. But it is his attitude toward the army surgeons that chiefly concerns the medical profession. He was the most obstinate opponent of all reforms proposed for the medical department of the army, and lost no opportunity of showing his dislike of the officers of that department. In this he was zealously seconded by Field Marshal Lord Wolseley, whose own almost bloodless campaigns had been successful largely owing to the perfection of the medical arrangements. Wolseley had a brother in the medical service and it has been suggested that this was the reason of his hostility towards the doctors whom he called and, as far as he could, treated as "camp followers." The Duke's dislike of doctors has in like manner been attributed to a rankling sense of resentment on account of the obligations under which he had been laid by one or two of their body. At the battle of Inkerman, as may be read in Kinglake's *Invasion of the Crimea*, 700 men of the Guards had to face some 7,000 Russians. The Duke lost his head and went away "for reinforcements" with the result that the troops were thrown into confusion. The situation was saved by Dr. Wolseley who brought out a portion of the force right through a heavy Russian column. According to Sir William Howard Russell, the correspondent of the *Times*, the Duke was a second time rescued from a position of extreme danger by the splendid courage of another medical officer, Dr. Wilson. Wilson, who was Surgeon to the 7th Hussars, was attached to the Brigade of Guards as a volunteer. For his exploit he received the thanks of the Duke at the head of the Brigade after the battle. Wilson is also mentioned by Kinglake as having done excellent service

by rallying the men of the Guards at one spot where no other officer was present. In spite of his acknowledgment made of Wilson's services and of a special mention of him in a private dispatch to Headquarters dated November 6, 1854, the Duke's real feeling would seem, from his subsequent conduct in regard to the medical department, to have been such as could scarcely be described as gratitude. Wilson himself, it is sad to relate, received no more solid reward than thanks and died a few years later in a madhouse, the close of his life having been darkened by disappointment.

Sir Donald Currie, one of our shipping magnates who got a title some years ago as a reward for taking Gladstone on luxurious sea trips, has given $500,000 to University College, London, for the erection of buildings in which to house a school of advanced medical studies on a site which has already been purchased. A sum of $100,000 is to be devoted to the establishment of a nurses' home in proximity to University College Hospital, and to provide accommodation for medical students attending poor women who take advantage of the benefits of the Maternity Department. The gift has been formally accepted by Lord Roseberry as Chancellor of the University of London and Lord Reay as President of University College. They express the opinion that the donation will help in directing the course of the University and College along the line of development by which London may be made the seat of a University worthy of the Metropolis and of the Empire. University College used to have the most brilliant staff of any of the London medical schools. The names of Sharpey, Burdon-Sanderson, Michael Foster, Wilson Fox, William Jenner, Russell Reynolds, Bastian, Gowers, Erichsen, Henry Thompson, John Marshall, Christopher Heath, Graily Hewitt and Tilbury Fox used to attract students from every part of the world. Within a very few years this galaxy of talent was scattered, and in spite of the accession of younger men like Thomas Barlow, Victor Horsley, Godlee, Sidney Martin, University College has never recovered its old position. With a new hospital which it owes to the liberality of the late Sir J. Blundell Maple and the new school for which Sir Donald Currie has now supplied the necessary funds, it may enter on a phase of more vigorous life. University College Hospital has a place of its own in the medical history of London because it led the way in throwing its appointments open to competition in the spirit of its motto *Palmam qui meruit ferat.* Before its day London hospital appointments were kept closely in the family, and even the resident posts were strictly reserved for the private pupils of the surgeons, who found the payment of a fee, varying from $2,500 to $5,000, a profitable investment. This, with many other abuses which made the London hospitals until near the middle of the last century hot beds of monopoly and privilege, has since been swept away so completely that it is difficult to realize that such a state of things ever existed.

OSTEOPATHY IN NEW YORK.

To the Editor of the Medical News:

Sir: A bill has been introduced in the Legislature of the State of New York, by Senator Fitzgerald, entitled, "An Act to Define and Regulate the Practice of Osteotherapy." It is Senate Bill No. 983, Introductory No. 761, and has been referred to the Committee on Judiciary, of which Hon. Edgar T. Brackett is Chairman.

This bill defines "osteotherapy" as follows: "The practice of osteotherapy is defined to be a system, method or science of healing disease without the use of drugs or medicine of any kind. It is based upon the proven laws of anatomy and physiology, and comprises scientific and thorough knowledge of the structure and functions of the human mechanism, to apply certain organic laws and natural remedial resources, within the human organism itself, and by means of scientific manipulations and adjustment, assist nature, in harmonious accord with its own mechanical principles, activities and processes, to recover from displacements, derangements, obstructions and pressures, and to regain normal equilibrium of form, action and function, thus restoring to the patient normal health and strength. The word 'osteotherapy' is derived from the Greek ('osteon,' bone, and 'therapeia,' nature, healing). The word 'osteotherapy' is a correction of the word 'osteopathy,' which latter means, translated from the Greek ('osteon,' bone, and 'pathy,' suffering), bone suffering. The word 'osteotherapy' embraces the science so-called osteopathy, the practice of massage and Swedish movements to its fullest extent, and any one practising the latter sciences, under those or different names, shall come under the jurisdiction of this act."

It is difficult to imagine this as a serious effort to secure legislative enactment, for to read the definition is "to laugh"; but we must assume that the gentleman who introduced the bill was not actuated by the desire to amuse his colleagues. The measure goes on to provide for a board of examiners, appointed by the Regents of the University of the State of New York, for examination and registration fees, and so on. If physicians will write to the members of the Senate Judiciary Committee opposing this bill, its fate will not be long in doubt.

If you will publish this letter, together with the inclosed reason why "osteopathy" and allied "pathies" should not receive special recognition, it will bring the matter before the profession, and, I believe, aid those who are endeavoring to protect our professional standards. One of the arguments used at the public hearings before our legislature is that other States have enacted laws recognizing the practises of "osteopathy," "optometry" and other peculiar methods of treating disease. I cannot believe that New York will ever enact similar laws unless some better reason than this is advanced. I do not believe that New York will enact any laws affecting the practice of the healing art unless the medical profession will endorse them. This opinion is the result of about eight years of more or less intimate acquaintance with our legislators, and, if it is correct, then, to use the language of the day, it is up to the medical profession to be alive to its responsibilities.

Very truly yours,

Frank Van Fleet, M.D.,

Chairman, Committee on Legislation, of the Medical Society of the State of New York.

"CLEAR" (?) VISION OF THE CAUSE OF MIGRAINE.

To the Editor of the Medical News:

Dear Sir: Presumably on the principle "Strike while the iron is hot," Dr. G. M. Gould follows up the recent issue of his "Biographic Clinics" by an article on the "History and Etiology of Migraine," *Jour. Am. Med. Ass'n,* Jan. 16 and 23, 1904.

His studied effort to attract attention invites scrutiny. All truth is welcome: but truth may be so presented as to conceal truth. Treatment of symptoms or coincident conditions may be so advocated and adopted as to delay the discovery of the real cause of those symptoms or conditions. Fearing this, I draw the attention of your readers to it.

I will premise by saying that I believe in correcting errors of refraction and getting all the good possible out of it. In this I approve of this writer's practice, even when it cures migraine, as I have no doubt it often does. But I cannot accept his conclusions which I here quote:

"The appalling mystery of thousands of years, especially of the last 300, the explanation of the one disease whose cause nature and cure are unknown, is now clear to all who wish to know, and whose minds are capable of receiving the truth. Migraine . . . . is but one of the manifestations and results of eye strain."

"It (migraine) may be cured by lenses correcting the astigmatism on which the disease depends."

Of "Biographic Clinics," unique and interesting in their human element as they undoubtedly are, it should be stated that their effort to make a post-mortem diagnosis has not the justification of the usual object of an autopsy, since it is not for the purpose of finding out the pathological condition of the bodies concerned, but to show that the subjects suffered from astigmatism. This is done by the aid of the anamnesis *without* physical examination. In a word, the writer has given us, not a *demanstration* but an *inference*. Inferences are captivating but dangerous. The vice of the inference is twofold: First, if not severely logical, it gives undue emphasis to an error; second, it readily becomes the ground of the familiar fallacy known as "begging the question." That is, in the present instance, the astigmatism would be assumed on the strength of the inference and employed with the force of a proposition. This writer, who, above all others, I would suppose to be on guard against this fallacy, falls into it immediately in this very article (p. 241) in these words: "At present all over the United States, there are quiet, almost unknown, *oculists, who are curing thousands of patients af the afflictions described in the fourteen historic instances* of the two volumes called Biographic Clinics." My italics show the application of the fallacy as well as if the writer had finished the sentence by adding to it the words "by lenses correcting their astigmatism." I am not disputing the alleged facts as to *cures* (which, however, I suspect may be only *inferences*), but merely pointing out the fallacy in the logic. This writer was at one time President of the American Academy of Medicine. If he could err so easily, how much more easily and unthinkingly could the majority of his readers.

As to the validity of his inference, that these "clinics" had astigmatism, observe: First, that he does not *prove* it, for that requires the demonstration on the living subject; second, that he does not argue to a legitimate conclusion, for that would require the logical use of facts that at present are against him.

For example, first, his own article furnishes the fact that migraine is due to other causes—instancing organic diseases; second, migraines, without organic discases, have been cured without the aid of glasses correcting existing astigmatism and yet with complete relief of the symptoms which the writer connotes under the term eye strain; third, there are cases of migraine without astigmatism, but with the symptoms of eye strain that have been cured without glasses (some of these very cases may be studied in the files of the Medical News); fourth, the seton has cured migraine; fifth, nasal operations are continually being reported to our State and National Societies that have cured migraine; and the list is still incomplete. But, any one of these facts invalidates his *inference*, so unduly and harmfully emphasized.

I would not be surprised to find in a school-girl's essay on migraine the use of such words as "appalling mystery," or the incorrect statement that it is the "*one* disease whose cause and nature and cure are unknown." And it would not surprise me that she regarded migraine as a *disease*, for she might even be familiar with the fact that Head had made some interesting pathological findings in the Gasserian ganglion in cases of migraine; but she might not know that even these had not been declared to be the seat of the disease of which the migraine was an expression. But I *would* be surprised if I found her loading her predicate with two such significant phrases as he employs in his conclusion: "The explanation is now clear to all (1) who wish to know, and (2) whose minds are capable of receiving the truth." Being of those whose minds are incapable of receiving this truth (?), I have taken the pains to place an interrogation mark after the word "clear" in the writer's predicate. The spirit manifested in these phrases is the same as seen in another quotation which I shall here make from this same article: "Their (the patients') official medical advisers derisively smile that old-time, tired, sneery, sickly smile." If, in spite of appearances, this writer is overpoweringly in love with *the truth*, I fear he is *not* overpoweringly in love with the other members of his own profession. The monograph on this subject by a distinguished specialist, which he admits is "erudite and cultured," he yet treats with the scant courtesy of the following words: "This bizarre theory, the latest result of critical science, does not need a word to demonstrate its absurdity."

One needs to know the causes, and I am aware how "eager has always been the search for etiology"; but I see here as did Jonathan Wright, from whose history I have just quoted, the need of wisdom and restraint in the search.

The writer withholds his name until the author of "Biographic Clinics" amends his mental attitude to his fellows in the practice of ophthalmology, and for the present signs E Pluribus Unum.

SOCIETY PROCEEDINGS.

THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS

Met in New York City, April 1 and 2, 1904.

The President, Eugene Hodenpyl, M.D., in the Chair.

Eck's Fistula.—The first paper was read by Dr. J. Edwin Sweet, of Philadelphia, on the technic of the operation known as Eck's Fistula. Dr. Sweet said that he had tried various methods in developing a more improved method of forming a direct communication between the portal vein and the inferior vena cava, but that his experiments on dogs had led him to prefer sutures of black silk in uniting the approximated walls of the vessels, and a specially arranged cautery for making the incisions in the vessel walls, which openings should not be less than two inches in length, to prevent subsequent portal congestion.

Coagulation of the Blood and Thrombosis.—This paper was read by Dr. Leo Loeb, of Philadelphia, who said (1) it is possible to obtain thrombi composed mainly of agglutinated blood-plates in animals whose blood has been made incoagulable by injection of leech extract. It is, therefore, probable that agglutination of cellular elements and not formation of fibrin is the primary factor in thrombosis; (2) an active influence of the endothelium of blood vessels inhibiting the coagulation of the blood cannot be said to exist. (3) The serum of the dog has an inhibiting influence on the effect of tissue coagulins

which themselves accelerate the coagulation of peptonplasma. This inhibiting effect is probably a specific one. (4) Organs undergoing processes inside the body which are similar to autolysis, have still an accelerating effect upon the coagulation of the blood (coagulative processes in infarcts). (5) Anchylostoma contains, mainly or entirely in its anterior part, a substance strongly inhibiting the coagulation of the blood. The existence of this substance is probably one of the causes of the anemia of anchylostomiasis. (6) The material covering the intestinal mucosa has a strongly inhibiting effect upon the coagulation of the blood, being thus able to restrict hemorrhages. The pancreas possesses the least coagulative power of all organs examined and is therefore relatively favorable to the occurrence of hemorrhages.

Amaurotic Family Idiocy.—Dr. William G. Spiller, of Philadelphia, reported the results of his microscopical examination of the material from a case clinically typical of amaurotic family idiocy. Only about eleven cases of this disease, with careful pathological reports, are to be found, and in few of these has the method of Marchi been employed. Hirsch's and Sach's cases are the only ones in which the extraordinary changes of the nerve cells, first described by Hirsch, have been observed. Dr. Spiller found all the nerve cells of the central nervous system intensely diseased. These cells were swollen, rounded, almost free of dendritic processes, and also of chromophilic elements, except about the nucleus. In many cells the nucleus was displaced to the periphery of the cell and the chromophilic elements remaining about the nucleus were granular. He also found intense degeneration by the method of Marchi. The pyramidal tracts seemed to have been longer degenerated in the spinal cord than in the brain, and it appeared as though the degeneration had begun at the portions of those tracts that were more remote from the cells of origin. The degeneration of the pyramidal tracts was of longer duration than that of the rest of the white matter. The lemniscus, the anterior cerebellar peduncles, the intrapontile part of the fifth nerve, the white matter of the frontal and occipital lobes and the paracentral lobule, the corpus callosum, a piece of the internal plantar nerve, etc., showed intense degeneration by the method of Marchi. Amaurotic family idiocy, he said, is a disease in which intense and widespread degeneration of nerve cells and nerve fibers occurs, and probably is the result of imperfect development of the nervous system, so that degeneration of this system begins within the first year of life. Dr. Spiller referred to two other cases reported by him previously with Dr. McCarthy, cases which clinically were not typical, and yet in these alterations of the nerve cells were like that occurring in this disease were found. No similar cases are known in literature. He suggested that, possibly, these might be regarded as aberrant forms of amaurotic family idiocy.

Hemolysis in Human Urine.—Dr. Roger Sylvester Morris, of Ann Arbor, Mich., read a paper on this subject. He said that in examining urines of patients with various diseases for the presence of hemolysins, negative results had been obtained except in cases of pernicious anemia, in which he had found that a very slight hemolytic action seemed to be present at times. This, he said, might be interpreted as supporting the theory advocated by Hunter and Warthin, that pernicious anemia is essentially the result of increased hemolysis.

Specific and Non-specific Agglutinins.—This was the subject of Dr. William Hallock Park, of New York, who said that a single variety of bacteria injected into a suitable animal (rabbit, goat, horse), excites the production of a number of agglutinins. One or more of these have an affinity for the bacteria injected or practically identical varieties, and for no others. These agglutinins appear to be truly specific, and can be absorbed only by the bacteria which excited them. Along with the specific agglutinins, others develop in the blood of the injected animals, which act upon other varieties than those with which the animal was immunized. These other varieties may differ greatly in their biochemical and pathogenic characteristics. If an animal is chosen whose serum does not as yet contain these common agglutinins, it will be found that there is at first a development of abundant specific agglutinins and a slight or moderate amount of common agglutinins. If the injections are continued, the common agglutinins may equal in amount the specific agglutinins. Thus the serum of a horse treated for a number of months with the Manila dysentery culture of Flexner clumped that bacillus in dilutions of 1 to 10,000, and also a variety of the colon group in the same dilutions. The serum of a goat treated with the colon bacillus clumped during the first weeks of treatment the colon bacillus only, and then later the Flexner bacillus in dilutions of 1 to 3,000. The colon bacillus at that time was clumped in dilutions of 1 to 5,000. As a general rule, the agglutinins produced in an animal through the injection of any bacillus can be exhausted from the serum by saturating it with sufficient quantities of that bacillus. Not only the specific, but the common agglutinins will thus be absorbed. All other varieties of bacteria will simply absorb the common agglutinins, the serum thus treated clumping now only the variety of bacteria injected. The lack of knowledge concerning the varying amounts of specific and common agglutinins in the serum of animals at different times during a long period of injections has led to many conflicting statements. Thus the various dysentery varieties were long considered to have identical affinities for agglutinins because the serum of horses rich in common agglutinins was used. Similar conflicting statements as to whether or not certain colon varieties had with typhoid bacilli common agglutinins are accounted for in the same way. The same gradual development of common immune bodies has been noted by us for rather closely allied bacteria, such as the dysentery bacilli and certain colon types. The serum of the injected animals protected at first only from the variety injected, but later from other varieties.

Degeneration of the Spinal Cord Produced by Repeated Injections of Cultures of Bacillus coli communis of Low Virulence.—This was the subject of a paper by Dr. G. A. Charlton, of Montreal, and was read by Dr. J. George Adami, who said that at a previous meeting of the association, Dr. Charlton had called attention to the grave anemia which can be produced in rabbits by repeated injections of both cultures of a colon bacillus (*B. coli communis*) of low virulence obtained from the intestinal canal of the healthy rabbit. An anemia characterized by poikilocytosis, and by a diminution of the red cells of 1,500,000, and of the hemoglobin to 10 per cent, which was recovered from when the injections were stopped and appeared again when they were renewed. In those animals in which the anemia was developed to a considerable extent, there appeared

a spastic condition of the hind extremities, followed by wasting of the muscles and eventual complete paralysis of an ascending type. Histological studies of the tissues of such animals showed (1) advanced atrophy of the affected muscles; (2) slight evidences of degeneration in the peripheral nerves; (3) some pigmentation and other indications of degeneration in the anterior horn cells and to a less extent in the posterior horn cells; (4) extensive degeneration, with sacculated appearance of the posterior and lateral tracts. The appearances in the cords closely resembled those seen in certain cases of pernicious anemia. These investigations, Dr. Charlton thinks, would tend to confirm the view that pernicious anemia and sundry ascending degenerations of the cord are of a low infectious origin.

On the Nature of Blood-plates.—Dr. Joseph H. Pratt, of Boston, in introducing this subject, said that the opinion so widely held by pathologists that blood-plates are degenerative products of erythrocytes is untenable. The structures formed from the erythrocytes by the action of hypertonic solutions of various salts bear only a superficial morphological resemblance to the true blood-plate, which is a definite element of the circulating blood. For the study and preservation of the blood, Dr. Pratt employs a solution containing 1.5 per cent. sodium metaphosphate and 0.65 per cent. sodium chloride. Perfect cleanliness of slides and coverslips is also essential or the plates may vanish almost instantly. The blood-plates never contain hemoglobin. They are always colorless and present a granular appearance and are flat. Films of blood stained with the eosinate of methylene blue show coarse granules in the plates which take the basic dye. The degeneration products of the erythrocytes, described by Arnold and W. Lasson, usually contain hemoglobin, later they become colorless. They are refractive and vary in size, are usually spherical in shape and never flat. By allowing a drop of 5 per cent. acetic acid to mix with sodium metaphosphate and blood Arnold's bodies are formed and can be compared with the blood-plates in the same preparation.

Experiments upon Agglutinins.—Dr. B. H. Buxton gave his conclusions after experiments upon agglutinins by Dr. V. C. Vaughan and himself. He considered three points in connection with work done on typhoid bacilli. Cultures of typhoid bacilli, he said, might be good or bad agglutinators, that on passing a good agglutinator through guinea-pigs it rapidly lost its agglutinability up to a certain point, that a serum which would agglutinate a good agglutinator at 1-20,000 might not agglutinate the same after passage through four guinea-pigs above 1-400. After passage through more guinea-pigs, however, up to ten or eleven, he had found that the agglutinability was not further decreased. He had found also that the serum of a rabbit immunized with a bad agglutinator had agglutinated a good agglutinator well and the culture of immunization badly. A good agglutinator, he said, would always agglutinate well and a bad agglutinator badly, no matter what the origin of the serum. He said that heat applied at 70° C. for thirty minutes slightly weakened the agglutinins, 75° C. applied for the same time changed them to agglutinoids, and at 80° C. they were destroyed. Heat applied to cultures at 70° C. and up to 100° C. modified the agglutinable substance (agglutinum) so that it combined with the agglutinum but produced no agglutination (agglutinumoids). The agglutinumoids absorb about as much agglutinin as normal agglutinum. Fresh emulsions of agar cultures in salt solution, when heated, produced similar results, except that the agglutinumoids absorbed much more agglutinin than the normal agglutinum. Agglutinums in emulsions in 1 per cent. formalin were not modified by heat up to 80° C., but they were destroyed at 100° C. and agglutinumoids were not formed. Dr. Buxton further said that simultaneous inoculations of different kinds of bacteria produced, in rabbits, specific agglutinins for each kind. A rabbit, he said, immunized simultaneously to typhoid and paratyphoid and cholera and pyocyaneus, on treating the serum with typhoid bacilli and filtering, the filtrate would not agglutinate typhoid but would agglutinate the other three as readily as the control serum. This was true, also, of any two or three, so that he had been able to absorb all but one in a similar experiment.

On the Coagulation Time of the Blood of Nephrectomized Rabbits.—Dr. S. J. Meltzer, of New York, said that in a series of experiments carried out by Dr. W. Salant and himself on nephrectomized rabbits, it was found that the clotting of the blood was considerably delayed in these animals. Forty to fifty hours after nephrectomy the coagulation time was nearly five times as long as that of normal animals. These results suggested, he said, an investigation of the clotting time of human blood in various forms of nephritis.

Dr. Pearce confirmed Dr. Meltzer's findings and said that these results were particularly true in hemolitic serum.

Experimental Study of Decapsulation of the Kidney.—Dr. I. Levien, of New York, reported on this subject. He said that surgeons had accidentally cured nephritis by decapsulation of the kidney, and that this had led them to recommend it in cases of acute inflammation of the kidney with colic. The function of the capsule had, heretofore, been unknown, and he had studied the kidneys of dogs in an endeavor to throw some light on this subject. The history of the capsule suggests, he said, that it performs other functions than those common to the capsules of other organs. A kidney having its capsule detached swells, hence it is influenced mechanically by the intact capsule. By means of an instrument, which Dr. Levien had devised, he had studied the pressure exerted by the capsule and had at the same time studied by means of sphygmographic tracings the pulsations of the capsulated and the decapsulated kidney, comparing them with the carotid pulsations. Pulsation ceased in the decapsulated kidney. His experiments were unfinished, but he believed that the capsule has great influence upon the kidney and suggested the probability of the wisdom of nephrotomy in preference to decapsulation in certain cases of nephritis.

Neuroglia, Myoglia and Fibroglia Fibrils.—Dr. F. B. Mallory, of Boston, demonstrated with the microscope, neuroglia, myoglia, and fibroglia fibrils.

Stain Applicable to Differential Leucocyte Counts.—Dr. Onuf, as a guest, gave a preliminary note on a stain applicable to differential leucocyte counts in the counting chamber. The procedure, he said, is the same as that in counting red cells. The blood is drawn up to the mark 0.5 in a red blood counting pipette, but instead of diluting with Gowers' or Toisson's solutions (up to the mark 101) a staining fluid of the following composition is used for dilution: (1) 12 per cent. formalin (Schering, 12 volumes; water enough to make 100 volumes), (2) 1 per cent. aqueous solution of sodium chloride (c. p.), (3) one-half per cent. aqueous solution of eosine (yellowish),

(4) Unna's polychrome methylene blue. Equal volumes of these four solutions are mixed, preferably in the succession above given and then filtered. The filtrate is the fluid taking the place of Gower's or Toisson's solutions in the pipette. It produces within fifteen to thirty minutes at ordinary room temperature, quicker at body temperature, a different stain of the leucocytes, bringing out the protoplasm, nuclei and granulations. Dr. Onuf said that further experiments, especially with regard to eventual application of the method to lesser dilutions of blood such as 1-100 or 1-20 are still pending.

Lesions of the Nodular Form of Xanthoma.—Dr. G. McConnell presented for Dr. Joseph McFarland, of Philadelphia, a series of lantern demonstrations of a histological study of the lesions of the nodular form of xanthoma.

(To be Continued.)

THE AMERICAN SOCIETY OF CLINICAL SURGERY.

Second Stated Meeting, held March 18, 1904.

The President, George Emerson Brewer, M.D., in the Chair.

First Day—March 18.

After the business meeting, which was held at the Medical Department of Columbia University, the officers and members proceeded to the demonstration room of Professor Huntington.

Tumors of Salivary Glands.—Dr. F. C. Wood gave a demonstration and discussed the general pathology of the mixed tumors which are so frequently found in the salivary glands. After a short résumé of the studies which have led pathologists to consider these tumors as endothelial in nature, the speaker called attention to the fact that many of these growths contained flat epithelium and well defined glandular structures. It is therefore necessary to assume that at least some of the tumors contain epithelium and it seems probable that a large proportion of the growths are composed chiefly of epithelial tissues derived from the embryonic epithelial structures which go to make up the salivary glands and not of endothelium. The complex nature of the tumors was, in the opinion of the speaker, best explained by the assumption of an error of development by which cartilage and other mesoblastic structures were left in close proximity to the glandular tissue at an early period of embryonic life and the derivation of the cartilage was most probably from that of the branchial arches. Attention was also directed to the congenital defects which were not uncommon in these regions, and in some cases were directly connected with the mixed tumors. A certain similarity between the structures described and those found in the teratoid growths from the kidney, ovary, and testicle, was also brought out. The speaker then mentioned some of the clinical characteristics of the growths, drawing attention to the fact that many of the tumors were benign and recurred only when incompletely removed. Even after a recurrence a fairly good prognosis could be offered after wide excision of the secondary growth. Specimens were also shown of true carcinomata, sarcomata, and adenomata of the parotid, to illustrate the differences in morphology between these growths and the mixed tumors, while the clinical differential diagnosis between the various growths was briefly touched upon.

Dr. Churchill Carmalt gave a demonstration of the accessory salivary glands. He showed a large amount of material, demonstrating the comparative anatomy of these organs and discussed their morphological relations and significance.

Modified Murphy Button.—Dr. Joseph A. Blake then inserted his modified Murphy button between the stomach and duodenum of a dog. This button consists of two small ordinary buttons linked together with very light bars. Its advantages over the round button lie in the large size of the opening which it cuts, and second in the fact that its shape should enable it to be more easily passed than the ordinary form. It somewhat resembles a modification suggested by Murphy, but differs from it in that it is lighter in construction and particularly in the size of the immediate opening which it creates, the passage in Blake's button being much the larger of the two.

Wounds of Arteries.—Dr. George E. Brewer then demonstrated his new method for treating wounds of the larger arteries. This consists in the isolation of the wounded vessel, in the removal of all particles of its sheath, in the rendering of it absolutely dry with ether and alcohol and in winding upon it a cylinder of an elastic adhesive plaster specially made for this purpose. The demonstration was on a carotid artery and proved eminently satisfactory.

Mr. Donald Gordon, Jr., the student assistant of the Surgical Laboratory, demonstrated an ingenious device which he has made to facilitate the application of the gum elastic to the vessel.

McGraw Elastic Ligature.—Dr. J. W. Draper Maury demonstrated a modified method of performing gastro-enterostomy with the McGraw elastic ligature. He showed a series of specimens which had been prepared in the last year at the Surgical Laboratory, representing an attempt to demonstrate that the ligature could be so placed as to punch out tissue after the manner of the Murphy button.

After this demonstration, the Society repaired to the University Club where luncheon was served.

Gastroptosis.—In the afternoon, a clinic was held by Dr. Ellsworth Eliot, Jr., at the Presbyterian Hospital. Dr. Eliot showed two cases; women who had entered the hospital, each suffering from symptoms which pointed clearly to gastroptosis. In each he had adopted a new technic which he will publish in full in the near future.

He then showed an Italian whose tongue had been resected by a modification of Kocher's technic. Dr. Eliot thought that this method would prove very serviceable in certain forms of carcinoma of the floor of the mouth and distinctly stated that its use was limited. He then showed two cases of resection of malignant growths in the bowel. One had occurred at a rather unusual position, viz., in the ileum. The other was situated in the colon. In each of these cases the method of anastomosis was by end-to-end ligation, a special technic, the details of which will soon be published, having been employed. He showed radiographs of an open safety pin in the bronchus, which proved that spontaneous version of the pin had been effected. Dr. Eliot then operated upon a case of appendicitis in order to demonstrate the technic employed at the Presbyterian Hospital.

The Society was then escorted to Roosevelt Hospital.

Facial Paralysis.—Dr. Robert F. Weir showed three cases of facial paralysis which had been treated by grafting a section of the hypoglossal into the facial nerve. The result of this technic has been very gratifying, and the promise for the operation is most encouraging. Dr. Weir then spoke most interestingly of a number of cases he had had years ago and gave the details of the removal of a large number of foreign bodies from the bronchi.

Enterostomy.—Dr. Blake then performed enterostomy with his new button in a case which had presented alarming symptoms of gastric ulcer.

Many of the members of the Society and several guests were then entertained at an informal dinner at the University Club.

Second Day—March 19.

Hernia.—At 8.30 A.M. the Society convened at the Hospital for the Ruptured and Crippled, where Dr. W. B. Coley gave a hernia clinic. He showed a number of cases in children and others upon whom he had operated a varying number of years previously, and then demonstrated with an unusual show of speed the technic employed in the treatment of hernia at this hospital.

The Society was then escorted to the Hudson Street Hospital, where Dr. P. R. Bolton showed a type of an "Emergency Hospital." He then took the members to the New York Hospital, where he gave an operative clinic and demonstrated a large number of cases upon whom laparotomy had been done through the transverse incision.

At one o clock luncheon was served at the Arena, and after this Dr. Howard Lilienthal escorted the Society to the new Mt. Sinai Hospital at Fifth Avenue and One-hundredth Street.

The next meeting will take place in October, one day to be spent at Buffalo, at the invitation of Dr. Roswell Park, and one day in Cleveland, by invitation of Dr. G. W. Crile.

BOOK REVIEWS.

The Practical Care of the Baby. By T. W. Kilmer, M.D., Associate Professor of Diseases of Children in the New York School of Clinical Medicine, etc. With 68 Illustrations. F. A. Davis Company, Philadelphia.

This is one of the most practical of the books on this subject it has been our pleasure to see. All the details involved in the care of infants are described with an attention to minutiæ which might seem meticulous to one who has not encountered the blunders which even intelligent people sometimes make when beginning the bringing up of children. The illustrations, for the most part photographs, are numerous and useful. Especially instructive is one series showing the proper method of clothing infants at different ages and seasons of the year. Feeding is discussed in accordance with modern teaching and the home modification of milk is elaborated with complete working directions. The ordinary complaints of babies are described and appropriate household remedies mentioned as well as the indications which require the presence of a physician.

We recommend it warmly as a guide to young mothers and to nurses.

Modern Surgery. General and Operative. By John Chalmers Da Costa, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital and to St. Joseph's Hospital, Philadelphia. Fourth Edition, Rewritten and Enlarged, with 707 Illustrations, some of them in Colors. W. B. Saunders & Company, Philadelphia, New York and London.

It is not altogether without regret that we see this book in its new form. Now that through rewriting and additions it has been brought into the class of the "big books" it has lost the great virtues of compactness and convenient size which it formerly possessed and which made it a wonder for the amount of information it contained in a small space. Still this disadvantage is more than compensated for by the new matter and new illustrations which have been added so that in its new dress of most artistic type it forms one of the most complete, practically useful and beautiful works on surgery at our command.

The progress of surgery is one of the notable events of the new century and it is interesting to see how closely abreast of the times the present volume is. The new vista which the studies of Ehrlich and others have opened up by their studies in immunity, hemolysis, etc., have received due recognition as well as the lessons military surgeons have learned in the treatment of gunshot wounds during the recent wars. The iodine sterilization of catgut devised by Claudius seems to have been overlooked in rewriting the section on suture material, though several others of the newer modern features are the descriptions of the baking apparatus for use in the treatment of joint affections and the new intestinal suture of Connell. Cystoscopy and prostatic surgery also receive up-to-date discussion.

It is a beautiful book and contains a higher percentage of actually useful, available information than many other medical works with which we are acquainted.

The Lymphatics. General Anatomy of the Lymphatics by G. Delamere; Special Study of the Lymphatics in Different Part of the Body by P. Poirier and B. Cunéo. Authorized English Edition. Translated and Edited by Cecil H. Leaf. With 177 Illustrations and Diagrams. W. T. Keener & Co., Chicago.

The anatomy and physiology of the lymphatics are being taken more and more into account in the surgery and medicine of to-day and any work such as the present which gives promise of more exact knowledge in these matters is to be welcomed gratefully. This volume which forms a section of "The Treatise of Human Anatomy," edited by P. Poirier and A. Charpy is divided into two parts. The first is concerned with the general anatomy and more particularly the histology of the lymphatic system while the second on the special lymphatics of the different sections of the body gives the regional distribution of the vessels and glands.

A large portion of the first part is given up to a very able discussion of our present knowledge of the leucocytes together with a most exhaustive bibliography of this subject. The minute anatomy of the lymphatics is treated with much clearness and the value of the letter press is greatly enhanced by numerous very good drawings, many of them colored.

The second half of the book has perhaps a more directly practical bearing and comprises researches of the greatest interest and value. Now that malignant disease of the internal viscera can be detected at a much earlier period and much more daring operative procedures can be attempted, the study of the lymphatic relationship of the organs becomes of the utmost importance in dictating the manner of operating and in indicating the chances of metastasis beyond the surgeon's reach.

The mechanical execution is excellent and the translation leaves nothing to be desired, so that it is a pleasure to commend the volume to all those interested.

Blood Pressure in Surgery. An Experimental and Clinical Research. The Cartwright Prize Essay for 1903. By George W. Crile, A.M., M.D., Professor of Clinical Surgery, Western Reserve Medical College, etc. J. B. Lippincott Company, Philadelphia and London.

The importance of this communication can hardly be overestimated. The therapeutic discord prevailing in our views as to the management of surgical shock and allied conditions is sufficiently shown by the almost diametrically opposed plans of treatment often advocated

by eminent men, sometimes even in the same hospital. The true significance of changes in blood pressure and the means at our command to combat abnormalities of this function have not received sufficient attention from a clinical standpoint at the hands of the experimental physiologists. The author has made this strangely neglected yet all important topic the subject of a most brilliantly conducted research and the startling nature of his conclusions, which appear almost heretical at first blush, proves how far from the truth our empirical observations have led us.

The book is divided into two general sections, the first devoted to the protocols of experimental work on 243 animals and the second to a more or less clinical study of the results obtained. The conclusions reached are so radical in nature that it is hardly fair to attempt to present them deprived of the experimental evidence which justifies them, but it may be said that in shock the essential phenomenon is a diminution of the blood pressure and that this is the result of exhaustion of the vasomotor centers. Strychnine, alcohol, nitroglycerin, amyl nitrite, are all either useless or even injurious, while saline infusion has a limited range of usefulness. Adrenalin in minute amounts administered continuously with saline solution (intravenously) gives excellent results with animals but its practicality has not yet been established. The most efficent means of restoring the enfeebled blood pressure to normal bounds is mechanically by encasing the entire body in a double suit of rubber between the walls of which air can be pumped and any desired pressure be produced and evenly distributed over the entire surface of the body. The method has found quite considerable clinical application with most satisfactory results.

The book is one that can safely be recommended to the thoughtful consideration of every one interested in major surgery, and, indeed, it is almost the duty of every worker in this field to acquaint himself with its contents, for it is only by extensive corroborative observations that a uniform system of treatment for this omnipotent enemy of surgical endeavor can be formulated.

A Manual of Operative Surgery. By Sir Frederick Treves, Bart., K.C.V.O., C.B., LL.D., F.R.C.S., Sergeant Surgeon-in-Ordinary to H. M. the King, etc. New Edition. Revised by the Author and Jonathan Hutchinson, Jr., F.R.C.S., Surgeon to the London Hospital. With upwards of 470 Illustrations. In two volumes. Vol. 2. Lea Brothers & Co., Philadelphia and New York.

What was said in regard to the beauty and excellence of the first volume of this magnificent work on its appearance a few months ago applies with still greater force to the present book. Such richness in paper and binding, such wide margins, such artistic typography and clean presswork have seldom been used in the embellishment of a medical work, while the reputation of the distinguished author is security for the fact that the jewel is worthy of its setting.

This volume is concerned principally with regional surgery and covers the wide field with a clearness of description and a directness in the choice of technical methods which shows the hand of the master at every turn. The one weak point lies in the sections on gynecology which, as is to be expected, are not quite up to the pitch of what our specialists have taught us to look for. With this exception the volume is most satisfactory and is pregnant with the forceful utterances of an authority.

The work is divided into the following sections: Plastic Surgery, Operations on the Neck, Operations on the Abdomen, Operations on Hernia, Operations upon the Scrotum and Penis, Operations upon the Rectum, Operations on the Head and Spine, Operations on the Thorax and Breast. Under these headings all of the important topics belonging to each are discussed in a most instructive and attractive manner. The chapter on excision of the tongue is particularly interesting; the author's preference is for a modified Whitehead operation preceded by a preliminary ligation of one or both lingual arteries with removal of the glands on the affected side. No application or dressing is applied to the stump of the tongue. Of the use of the cold loop or galvanic écraseur in these cases he says, "As a surgical undertaking *excision by the écraseur* has about it a distinct air of senility."

In the chapters on intestinal surgery full descriptions of the various applications of the Murphy button are given but, like most modern operators, the author prefers to dispense with it where possible. Under renal surgery we find no mention of the question of decortication for nephritis and the author differs from American surgeons in advising against passing the sutures through the separated capsule in nephropexy. The discussion on prostatic operations is not quite as modern as might be desired, as no mention is made of Bottini's operation with its numerous modifications. A suggestion that has much to commend it is the one that after breast operations the dressing be applied so as to keep the arm away from the side and allow motion at the elbow.

In every way the work fulfils any demands that may be made upon it; it is sufficiently lucid and simple in style to be agreeable to the student, and yet sufficiently technical to be of the utmost value as a book of reference to the occasional operator or to the specialist, who will find the many references to the literature most useful. Added to this is the sumptuous execution which, for a bibliophile, makes it a pleasure simply to handle the volumes.

The Man Who Pleases and the Woman Who Charms. By John A. Cone. Hinds and Noble, New York.

This interesting little book, contains a number of very practical hints with regard to that most important of qualities—how to be agreeable. Tact is said to be the basis of many a professional man's success. Unfortunately it is said to be one of the things that is inborn and cannot be acquired. There is no doubt, however, that where something of the quality exists already it may be improved by proper direction, and that even a very good imitation of the real article is not impossible for those who cultivate the realization of the significance of social usages. Mr. Cone's book may very well serve as a manual for those who feel the need of a guide, not in the ways of polite society, but of living in such a manner as to make life as pleasant as possible for those around them.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Medical Union No. 6. W. H. King. 12mo, 58 pages. Monograph Press Co., New York.

International Medical Annual, 1904. 8vo, 770 pages. Illustrated. E. B. Treat & Co., New York.

The Life of Wm. Pepper. By F. N. Thorpe. 8vo, 555 pages. Illustrated. J. B. Lippincott Co., Philadelphia and London.

VOL. 84. NEW YORK, SATURDAY, APRIL 16, 1904. NO. 16.

ORIGINAL ARTICLES.

ULCER AND CANCER OF THE STOMACH FROM A SURGICAL STANDPOINT.

BY WILLIAM J. MAYO, A.M., M.D.,

OF ROCHESTER, MINN.;

SURGEON TO ST. MARY'S HOSPITAL.

THE most important subject before the medical profession to-day is that of diseases of the stomach. Heretofore they have been considered almost entirely from a medical point of view and it is only of late that their surgical possibilities are beginning to be recognized.

The treatment of gastric disorders has been based upon chemistry, and for two decades hydrochloric acid and pepsin have formed the chief ammunition which has been fired at diseases of the stomach. During this time there has gradually developed a feeling that these means were inefficient and while many have turned toward new pharmacopeal combinations, there has also been an intelligent effort, not toward drugs, but rather to a better understanding of the functions of the stomach, and with this a different theory as to its pathology. It is the mechanics of the stomach which is usually at fault and not its chemics, and it is for this reason that surgery is rapidly invading the field. I would not be understood as saying that even the greater proportion of diseases of the stomach are surgical; but that the majority of serious lesions may become so can not be doubted, and it is also true that a very large proportion of chronic gastric disorders are due to faulty mechanics and must call surgery to their aid.

The stomach can be aptly compared to the magazine of a coal-stove into which at intervals there is rapidly placed a quantity of material for digestion. While it absorbs fluids and equalizes the temperature of the ingesta, it does not *digest* the food; but with a weak solution of pepsin and hydrochloric acid it *macerates* the ingested material, and the pyloric portion breaks up the food masses by a grinding motion. As the process is completed the product is turned into the small intestine where digestion and assimilation is accomplished.

The muscular action of the stomach is of a twofold nature, the fundus contracts rather slowly upon the food material, forcing it toward the pyloric ends, which grinds and pulverizes it into a harmonious whole, the fundus being the hopper, and the pyloric portion the grind stones. It can readily be seen that an obstruction at the outlet produces dilatation with retention or stagnation of the food, and this often results in fermentation and absorption of deleterious products. The extent of the disorder depends upon the degree of obstruction and the compensatory hypertrophy of the musculature of the stomach. Many of these cases develop a degree of hypermotility which equalizes the obstruction. In other cases a period of compensation alternates with muscle failure, exactly like valvular heart lesions and their effect upon the cardiac muscle. We see the same phenomena in obstructions at the outlet of the gall-bladder, and at the pelvis of the kidney, and again in the urinary bladder—all organs with a temporary storage function and a limited outlet. Even with moderate obstructive dilatation the victim begins to diet and in the main "diet" means restricted food supply, the attempt being to reduce the amount of work to be done to the minimum. In the extreme cases, the solids are first eliminated from the dietary because, as has been pointed out, the stomach does not assimilate such articles of food and the bulk increases the difficulty of passing the obstruction. Fluids, on the contrary, are absorbed to a certain degree in the stomach and also more easily pass the contracted outlet. Therefore, foods with much fluids and little residue are chosen.

The stomach may become enormously distended and even the absorption of fluids be reduced to small proportions. So true is this, that Crämer was able to demonstrate by the quantity of urine passed, the degree of dilatation and the amount of gastric function. He divides these cases into three grades, as shown by the urine collected for twenty-four hours. First degree, 1,500 to 1,000 c.c.; second, from 900 to 500 c.c., and third, all cases falling below 500 c.c., and further says that lavage of the stomach which contains much material, with urine below 500 c.c., may dilute the toxic products in the stomach and render them more readily absorbable. Tetany has its onset immediately following the use of the tube in many reported cases. The stomach should be emptied some hours before lavage is practised in such cases. That these products of retention and fermentation are poisonous cannot be questioned. We had one case in which gastro-enterostomy turned a great amount of such material into the small bowel and the patient promptly died from toxemia, which followed the absorption. The symptoms resembled the effect of cadaverin upon animals. Gastric tetany probably depends for its origin upon the absorption of retention products. The severe grades are the only ones which we have heretofore recognized. They have been exceedingly serious, as Albu in forty cases found thirty-one deaths. Mild grades, however, are much more common and apt to be overlooked. Muscle twitching, prickling sensations and so forth in connection with serious dilatation are to be looked upon as a warning and surgery should not be long delayed. Crämer has recently written exhaustively upon this subject.

The popularity of the stomach tube depends upon the mechanical removal of food remnants which would otherwise stagnate in the stomach; but it does not cure any more than the catheter used to relieve urinary retention or residual urine, cures the prostatic hypertrophy upon which the condition depends. It relieves the temporary obstruction and may aid restoration of compensation by giving time for muscular development; but our faith in the ability of gastric lavage, either plain or medicated, to cure mechanical obstructions has been shattered beyond repair.

It is not my purpose to discuss in detail the nature of the various obstructions, but rather to indicate the effect of such interference upon gastric motility and to call attention to the fact that serious or progressive obstructions are surgical conditions and that dilatation of the stomach and its degree is the sign post which tells us the proper course of action. If the lesser curvature is in normal position and the greater curvature of the stomach lies below the umbilicus, some degree of dilatation is present. If the stomach is prolapsed, the distance between the curvatures, demonstrated by air inflation, will readily show the amount of dilatation. The tartaric acid and bicarbonate of soda test is sudden and in certain cases has danger of rupturing a weakened gastric wall. With an ordinary Davidson syringe or bicycle pump and a stomach tube, the stomach can be easily filled with air and its outline marked upon the skin. Crämer says that any dilatation not vastly improved in four weeks under gastric lavage, dietary and massage for muscle building, should be subjected to operation. Loss of stomach motility in its lesser degrees, is not necessarily obstructive. For instance, in gastric atony and in the neurasthenic state, loss of motility is not infrequently neurotic in origin and often accompanied by hyperchlorhydria. These conditions carry with them stigmata that will not be easily overlooked and stagnation and retention of food does not occur for any length of time in such cases.

Turning from the most common causes of interference with the function of the stomach, due to obstruction of outflow, we come to the second great class of gastric disorders in which disease of the wall of the stomach prevents its reservoir function or limits its grinding power, that is ulcer and cancer of the stomach. The most common seat of these lesions is in the pyloric portion and they are intimately associated with the etiology of the obstructions, deformities and tumors upon which the dilatation depends. These latter conditions are to be looked upon as a result of ulcer or cancer of the stomach. There are, of course, many other causes of obstruction, such as valve formation at the pylorus, but they are the exceptions which prove the rule.

Ulcer of the Stomach.—Simple ulcer of the stomach is by no means the rare condition which we have been led to believe. The acute form with its classical symptoms, pain, vomiting, hemorrhage, local tenderness and hyperchlorhydria form a group of symptoms which is readily recognized, and the treatment is purely medical. Surgery has only to do with the complications, such as hemorrhage or perforation. It is altogether probable that the vast majority of acute ulcers heal, but a considerable minority fail to do so and constitute a share of the chronic ulcers.

Acute exacerbations of a chronic ulcer must not be mistaken for acute ulcer as is too often done, and the subsidence of the acute period taken for cure of the original condition. Chronic ulcer is frequently, if not usually, chronic from its inception, its course being marked by a period of symptoms lasting from a few days to weeks, to be followed by a longer period of apparent betterment, lasting some weeks or months. These patients go from one physician to another, each acute attack a medical cure, it is the old story of appendicitis and gallstones over again. Failure to stay well impels the victim to seek new aid and often enough each physician believes the cure to have been permanent. Ultimately the patient, unrelieved by legitimate medicine, much to our disgust, takes to the charlatan and patent medicine vender. These cases are surgical. They are chronic because treatment has been tried over and over again and has failed.

Etiology.—The etiology of gastric ulcer is obscure. There are three known factors of great importance: first, anemia; second, hyperchlorhydria; and third, mechanical injury. Anemia is certainly a very important element, particularly at the inception of the disease, a cute round ulcer being by no means a rare occurrence in the chlorotic state and the overcoming of the anemia often does much to establish a cure. In the chronic forms this anemia may be continued and depend upon a slow loss of blood. Murphy has pointed out its close resemblance to the pernicious type. In some cases the post mortem is the only way the diagnosis has been cleared up.

Hyperchlorhydria usually exists at some time in the history of peptic ulcer and in most cases at all times. That it is of the utmost etiological importance is shown by the frequency of duodenal ulcers of the peptic type above the opening of the common duct, with its alkaline discharges, and the occurrence of secondary peptic ulcer in the jejunum at or near the opening made by gastroenterostomy for drainage of gastric ulcer.

Mechanical injury is also an important factor as shown by the location of 75 per cent. of gastric ulcers in the grinding apparatus of the pyloric end of the stomach, although having not more than one-sixth of the exposed mucous membrane. It is for this reason that gastrojejunostomy has given such signal relief. The anemia is overcome by good feeding, the hyperchlorhydria by the rapid drainage of the gastric juices into the intestine with its alkaline secretions, and lastly the avoidance of irritating the ulcer by the passage of food over its sensitive surface.

Ulcer of the Duodenum.—Chronic ulcer of the duodenum should be classed with gastric ulcer and occurs in the first 2½ inches of the intestine.

It is essentially a disease of adult males. In 39 cases which have come under our care at the operating table, 32 were in males. In proportion to its frequency it is even more liable to perforation than gastric ulcer but also more frequently walled off because of its anatomical relations and its more fixed position. In some instances the symptoms of chronic duodenal ulcer cannot be distinguished from gall-stone disease, the location and the colics being strongly suggestive of biliary calculi. We have on several occasions operated for gall-stones and found duodenal ulcer. The pain and local tenderness, however, usually lasts longer in the latter disease. Of the combined series of gastric and duodenal ulcers which occurred in our experience, 12 per cent were duodenal, 88 per cent. gastric.

Symptomatology of Gastric and Duodenal Ulcer.—The symptoms of chronic ulcer are variable, but the chief one is pain,—painful digestion, not all the time, perhaps, nor at every meal; but a feeling of discomfort a considerable part of the day and at times severe cramp-like pains which in ulcer of the pylorus may amount to a sharp colic. If the ulcer extend to the peritoneum, symptoms of regional peritonitis may come on, lasting several days or, more rarely, leading to unprotected perforation. Points of perforation are usually protected, as shown by the frequency of extensive adhesions. Fortunately, in the large majority of cases of gastric and duodenal ulcer, the secretions are excessively acid, therefore relatively sterile, and general infection is less liable to occur than further down the intestinal canal. Vomiting is a late symptom and depends upon a complicating stenosis in the majority of instances. Hemorrhage in appreciable quantities is rare, although many anemias depend upon a continuous small loss of blood. As the majority of symptom producing ulcers are in the pyloric end of the stomach, the syndrome of Hartmann is usually present, that is, pain, hyper-secretion, gas and indigestion. Ulcers in the body of the stomach are frequently latent and the first knowledge of their existence may be a fatal perforation. Welch, in 793 cases, found 235 posterior, 288 lesser curvature, 96 anterior wall, 95 pyloric ring, while only 29 were found in the fundus and 27 along the greater curvature. It is interesting and surgically very important to note that in at least 20 per cent. of cases, more than one ulcer is present. A frequent combination is one ulcer anterior and another facing it on the posterior wall, or one or more ulcers of the stomach and one of the duodenum. Brinton, in 463 autopsies upon cases with ulcer of the stomach, found 57 with two ulcers, 16 cases with three or four, two cases with five and four cases with more than five.

Chronic ulcer is a disease of adult life and is comparatively rare in youth. The small, round and fissure ulcer is most frequent in the female, while the large irregular ulcer is more common in males. Friedler, in 2,200 autopsies found 20 per cent. of the female bodies with evidences of ulcer, and only 1.5 per cent. of men. Berthold, in 262 autopsies of ulcer cases, found 134 women and 128 men. Welch, in 793 autopsy findings, gave 60 per cent. women and 40 per cent. men, and this latter agrees very closely with our experience in somewhat over 300 operated cases. The series of large chronic irregular ulcers tabulated by Seymour Taylor gave 72 males and 28 females. This also agrees with our experience, although the preponderance of males was not so great.

The diagnosis of chronic ulcer is essentially clinical. The history and the physical examination, including outlining the stomach by air distention with the use of the stomach tube to develop stagnation or retention, give the most important evidence. The laboratory findings, while not worthless, are often contradictory and misleading. In over 1,500 cases which have been examined by my colleagues, Drs. Graham and Millet, 478 came to operation. The only test which had even corroboratory worth was that high values for hydrochloric acid argues for ulcer and low values for cancer; but even this is not to be relied upon. Otherwise, the microscopical and chemical findings, with the exception of the occasional presence of blood, were practically worthless. I do not wish to condemn such attempts for they will lead to great good and should be encouraged by all means; but at the present time we must be careful and not ask the laboratory to make our diagnosis, for if we do, we will ask in vain.

It should not be forgotten that ulcer of the pyloric portion of the stomach may form a well defined tumor and the anemia from chronic blood loss develop a cachexia which, with the tumor, may give the appearance of gastric carcinoma in a hopeless stage. No doubt many of these cases have died from a condition which was essentially benign. We have but to look over the literature to see the frequency of this mistake, a gastro-enterostomy permanently curing a patient in whom a supposed malignant tumor with stenosis proved to be benign.

Prognosis.—The mortality of chronic ulcer is given by Leube at about 25 per cent and he states that about half of the remainder will be cured. Debove and Remond estimate that 25 per cent. die directly from the lesion (hemorrhage perforation and so forth) and 25 per cent. additional from complications, such as tuberculosis induced by the anemia. In 500 cases reported recently at the London hospital, 211 were known to have had previous attacks, 18 per cent. died and 42 per cent. were not cured at the time of discharge, leaving 40 per cent. supposed to have been cured. There is also the further danger of cancer grafting upon ulcer base which is undoubtedly of frequent occurrence, although years may have elapsed between the ulcer and the malignant change. Graham, in 157 cancers of the stomach which came to operation at our hands, found a good ulcer history in over 60 per cent., although perhaps the malignant degeneration developed

years after the ulcer had healed. Futterer, Dunn and many others also insist upon the etiological importance of ulcer in cancer of the stomach.

Surgical Indications.—This leads us directly to the query, When should gastric ulcer be surgically considered? Leube says that from four to five weeks should cure gastric ulcers which can be cured medically. For those cases which have not developed obstructions, it would be best to try a Leube treatment (rectal feeding and so forth), but the bulk of these cases have employed various forms of treatment usually to temporary advantage; but with lack of permanent benefit, and are already in the chronic state. Such cases should be considered surgically and especially so if secondary complications, such as obstruction, dilatation, adhesions and deformities have developed.

Indications for the surgical treatment of gastric ulcer can be divided into two distinct classes; first, the ulcer itself; second, the complicating adhesions, deformities, obstructions and so forth. There are clinically three varieties of gastric ulcer: (*a*) The mucous erosion, limited to the superficial epithelium of the mucous membrane. (*b*) The round and fissure ulcer which is probably the most frequent and is limited to the mucous coat, excepting in perforative cases. It has the distinctive feature that it cannot often be located from the exterior of the stomach, sometimes a little thickening can be felt or some point at which the mucous coat does not glide on the peritoneal and muscular tunics in the normal manner. This variety of ulcer is often multiple and may lead to unpleasantness at the operating table—an ulcer accurately diagnosticated cannot be demonstrated to the mortification of the surgeon. (*c*) The large irregular ulcer invading all the coats of the stomach and easily recognizable by its thickness and the milky or opaque appearance of the peritoneum. This variety is often mistaken for cancer, especially as enlarged lymph nodes are to be found in the omenta, particularly in the gastrocolic omentum as pointed out by Lund.

The complications of gastric ulcer are many. For instance, adhesions, the separation of which may give relief but is open to the objection that it leaves the ulcer which caused the trouble uncured so that the adhesions usually reform. Separation of adhesions must be done most carefully, as it may be found that they have protected a perforation which may unfortunately be opened up. Obstructions usually exist at the pylorus but may obtain in the body of the stomach, forming an hour-glass contraction.

Gastric Drainage.—The keynote to the surgery of gastric ulcer is drainage, and the best place for this is to the left of the muscular pyloric portion. There are four methods of inducing gastric drainage: (1) The Heinike-Mikulicz pyloroplasty, which does not give satisfactory ultimate results in more than 70 per cent. of the cases. It has the misfortune of leaving the enlarged opening at a high level so that if the stomach be greatly dilated, the degenerated muscle must elevate the food to the high lying outlet. There are also liable to be firm adhesions binding it to the surrounding tissues. (2) Finney's gastro-duodenostomy. This is a most excellent operation, giving a large opening in the line of drainage. It is most useful in narrow strictures and least successful in open ulcer, as the food must pass the ulcerated area to reach the outlet. (3) Rodman's operation. Excision of the ulcer, would seem to be indicated in a large number of cases; but if so it must be combined with gastro-enterostomy, (*a*) because there may be more than one ulcer, (*b*) because a stricture often follows at the site of incision, no matter how made, (*c*) because it leaves the tendency to ulcer unchecked and new ulcers may form. Rodman suggests that the most sensible thing to do is to excise the entire pyloric end of the stomach, the so-called ulcer bearing area, closing the duodenum and stomach end permanently, and then do a gastrojejunostomy in the usual manner. This would meet all the objections to the excision of the ulcer and avoid the possibility of secondary cancerous change. (4) Gastrojejunostomy. All in all this method meets the indications most perfectly, although it is probable that Rodman's operation will be often considered in the near future.

There have occurred in the surgical practice of my brother, Dr. C. H. Mayo, and myself, up to April 1, 1904, 328 operations for the improvement of gastric drainage, divided as follows: 20 pyloroplasties, no deaths but seven secondary operations. Finney gastroduodenostomy, 40 operations, one death, no secondary operations. Gastrojejunostomy, 271, mortality in the benign series six per cent., with six per cent. of secondary operations; of these five were subjected to Rodman's operation. In the malignant cases there was 23 per cent. mortality after gastrojejunostomy. Our preference for ulcer is the posterior operation made by means of the suture, reserving the anterior operation either with the Murphy button or the McGraw ligature for the cancer cases and such cases of benign disease as present unusual difficulties to the posterior operation.

Cancer of the Stomach.—Gastric carcinoma is the most frequent form of cancer met with in the human body, statistics ranging from those of Welch who gives it as 21.4 per cent. of the total and second to the uterus, to Virchow who places it first at 31 per cent., and Haberlin at 40 per cent. of the total number of cases. Why has there been so little attempt made to cure these patients by the only known means, a surgical operation? There are three reasons for this conservatism, first, a belief that cure cannot be accomplished; second, that the mortality of radical operations is almost prohibitory; third, that the diagnosis cannot be made until the case is hopeless. Let us discuss these reasons more in detail.

First.—Can cure be accomplished by operation? McDonald found 43 cases cured by operation which could not be disputed; Murphy collected 189 cases operated upon radically by Krön-

lein, Maydl, Rydygier, Czerny, Morisson, Bevan and Mayo, with 26 deaths. Of these 17 survived three years, about eight per cent. This was reduced to five per cent. by recurrence after three years; but as many of the cases were alive and well more than two years, enough of these cases would by the law of averages survive to bring the percentage up to eight per cent. or more. Not only that, but Krönlein statistics demonstrated an average prolongation of life of fourteen months over the unoperated cases. Mikulicz, in 100 resections, had an average duration of life of one and one-third years. In our own experience of 43 radical operations for malignant disease of the stomach, all but two who survived the operation, lived beyond the year; one lived three years and seven months and several are alive and well more than two years after.

Second.—Is the mortality prohibitory? Billroth had a death rate of 60 per cent. He said shortly before his death that his later years had been sorrowed by the vast number of almost hopeless cases of cancer that appeared to be attracted to his clinic, and speaking of operations for gastric cancer said, "They left the operating table in shock, from which some of them recovered." These cases went to Billroth because he was almost the only one who gave them any chance.

The mortality depends largely upon the case. In an early operation upon a patient not materially reduced, the mortality will not exceed 10 per cent., and the average mortality at this time, taking the good and bad cases as they come, is not above 20 to 25 per cent. Much of the danger depends upon the adhesions to neighboring viscera. Haberkant had a mortality of 72.7 per cent. with adhesions and 27.3 per cent. without. Mikulicz had a mortality of 70 per cent with adhesions to the pancreas and 23.5 per cent. without such adhesions. In the 189 cases by seven operators quoted by Murphy, the mortality was only about 15 per cent.

Third.—Can the diagnosis be made in time by medical means? To this I say most emphatically, No, it can be surmised, but not often diagnosticated with certainty. Exploratory incision is practically harmless and a suspicion of gastric cancer should cause us to lay the facts before the patient and his friends and let them decide whether the only means of making a diagnosis shall be undertaken or not.

There are two points in the diagnosis upon which I wish to dwell, because I believe that their significance has been exaggerated. First, as to the presence of a tumor. It has been said that a tumor of itself marks inoperability. This is not true, a small movable tumor in the region of the pylorus is a favorable indication, because while cancer of itself does not give evidence of its presence in an early stage, the tumor does by giving obstructive symptoms which call attention to the mechanical conditions present. As a matter of fact, it is only those cases located in the pyloric region which are amenable to surgical intervention. This part is accessible to palpation and also to operative procedures. Pyloric cancer, by its location, introduces mechanical features which enable an early diagnosis. I would say here that the pylorus normally is near the middle line, rather than to the right as we have been led to believe, and also that the stomach lies in a much more vertical position than has usually been pictured, so that the pylorus is not much above the lowest point of the normal stomach.

In our experience, the larger number of cases with symptoms of gastric cancer in which no trace of a tumor was present at the pylorus and without symptoms of obstruction, have proved to be hopeless cases of cancer of the body which gave no early symptoms.

The second point upon which I wish to speak is that laboratory diagnosis of cancer of the stomach has little importance during the operable period because the disease is of too slight extent to interfere with the secretions. When it does so it usually means a hopeless involvement.

Radical extirpations of gastric cancer follow modern lines. The necessity of removing the regional lymph structures is recognized just as it is in the cancer of the breast. The first great improvement was due to the researches of Mikulicz, who showed that the blood vessels and lymphatics of the lesser curvature lay in the stomach wall and that it was necessary in every case to remove all of the lesser curvature, even if the growth was small and confined to the pylorus. Cuneo demonstrated that the glands of the greater curvature were near the pylorus and that the lymph current of this region was from left to right, showing that it is not necessary to be so radical on the greater curvature, especially as the blood vessels are set at some distance from the greater curvature to allow of rapid expansion and contraction of the stomach. The lymph nodes in this situation are set free from the gastric wall with the blood vessels. As to the operation itself, by tying the four blood vessels supplying the stomach at proper points, the extirpation can be made practically bloodless, much as in abdominal hysterectomy. The duodenum beyond the growth and the stomach at a healthy point proximal to it should be doubly clamped and the diseased part cut out with the actual cautery one-fourth inch from the holding clamps, preventing inoculation of the cut surfaces with cancer. The seared stumps should be sutured with catgut at once before removing the clamps, thus checking the hemorrhage, and preventing soiling of the field from the otherwise open viscera. Lastly, both the doudenal and stomach ends are buried by silk or linen sutures and an independent gastrojejunostomy made. Such an operation in a case suitable for extirpation can be done in an hour without loss of blood or shock. We have made pylorectomy and partial gastrectomy 43 times with seven deaths.

In conclusion let me recapitulate: Cancer of the stomach can be cured without excessive mortality only when exploratory operation is under-

taken. We will not discuss the palliative operations, as they are at best but a prolongation of a hopeless existence.

OTITIS MEDIA IN CROUPOUS PNEUMONIA; WITH THE REPORT OF A CASE OF ACUTE SUPURATIVE OTITIS MEDIA PRECEDING THE PNEUMONIA.*

BY NATHAN G. WARD, M.D.,
OF PHILADELPHIA;
OTOLOGIST AND LARYNGOLOGIST TO ST. AGNES' HOSPITAL.

It is well known that otitis media may be a complication or sequel to any severe systemic disease, especially the acute infections. The relationship of the otitis to the systemic condition may be as follows: (1) One who has otorrhea develops the systemic infection; (2) one who has otitis previously but has been apparently well for a long while suffers a recurrence; (3) otitis as a primary manifestation, the systemic disease following; (4) otitis as a complication or sequel to the systemic infection; (5) the otitic infection as a cause of the systemic infection or general pyemia.

To take up these headings separately in reference to pneumonia, the figures referring to the headings as enumerated above, we note:

1. One condition may have little or no influence on the other, but more frequently the otitis is made worse by the pneumonic infection.

2. When one who has had an otorrhea during childhood, although for a long time it may have remained apparently well, free from discharge or pain, a recurrence during the pneumonia is frequent. It has been experimentally shown that the pneumococcus injected in the blood is far more likely to attack any part previously damaged by injury or suppuration than one the resistance of which has not been lessened. Meltzer[1] cites several cases where the pneumonia was preceded by a severe otalgia; all had had otitis media previously in the now aching ear. In all at the outset of the pneumonia, earache was the predominant symptom, this predominance, however, never lasted longer than one day. The pain disappeared on the second or third day or it lost its intensity and finally disappeared shortly before the crisis set in or with it. In none did the earache terminate in discharge. In one of Meltzer's cases the earache, preceding the pneumonia was so striking as to so deeply impress the mother that when one year later the boy had an earache, she sent for the doctor and said the boy again had pneumonia. Her guess proved correct.

3. There may be a simultaneous infection of the ear and lung. In a few cases the ear symptoms are manifested first. This was true in my case. The ear manifestations may be so severe as to so completely overshadow the lung process, that the pneumonia is not suspected until the otalgia is relieved by incising the membrana tympani or its spontaneous rupture. My case is an example of this.

4. The otitis may be secondary to the pneumonia, and this is their most frequent relationship. During the period of expectoration, the pneumococcus brought up by coughing, enters the nasopharynx, gains access to the Eustachian tube, extends by contiguity of tissue to the middle ear, and starts a suppurative otitis media. The occurrence of this complication during the height of the pneumonia, at the time when the patient's mind is dull and perhaps stupid or delirious, pain in the ear is not complained of, and the physician's attention is directed to the lung condition he attributes the symptoms of cerebral irritation and septic infection to the severity of the pneumonia. Hence the ear inflammation is unrecognized until the drum ruptures, revealing the middle-ear suppuration, or it is discovered at the autopsy.

5. In one of Wilson's[2] cases, the otitis was revealed at the autopsy, not being previously suspected. At the post mortem, consolidation and small abscesses in the lung were found. The middle ear was filled with foul-smelling pus. The pathological changes in the tympanum showed a suppurative process that had evidently existed much longer than the pneumonia.

Frequency of otitis in pneumonia.—Otitis media complicates pneumonia more often than is recognized. This is evidenced by autopsies held on cases that have died from pneumonia and by examining the ears of a series of cases of pneumonia. In most of the statistics lobar pneumonia was not differentiated from bronchopneumonia. The following statistics taken from Meltzer's and Wilson's articles, include both types:

In Netter's 20 cases of otitis, 14 had pneumonia; in Hartman's 36 cases of otitis, 10 had pneumonia. Rasch's 43 cases of pneumonia, 42 had otitis; Teichman's 73 cases of pneumonia, 34 had otitis and Wilson's 71 cases of pneumonia, 8 per cent. had otitis. Ponfick's 11 autopsies on pneumonia cases, 10 had otitis.

In the five of Wilson's cases, whose ears were examined at the autopsy, three had suppurative otitis media, which, apparently, was the cause of the pyemia that brought about the fatal result.

In a search of the literature I failed to find a single case where there was a simultaneous infection of the ear and lungs; the ear manifestations preceding the pneumonia. I wish therefore to record the following case. The otitis for two days entirely overshadowed the pneumonia; the latter not being suspected until the ear was relieved by incising the membrana tympani.

Case.—G. M., male; physician. Never had otitis media previously. On the night of Jan. 11, 1903, he was awakened with severe pain in the left ear, which prevented further sleep; some fever. I saw him in the afternoon of Jan. 12. The only symptoms complained of was a dull aching pain in the left ear. Temperature, 102° F., pulse 90, respirations 27. The tympanic membrane was red and injected but there was no bulging or other evidence of fluid in the middle ear. Nasal examination revealed slight coryza, septum deviated to the right, and right nasal obstruction.

* Read before the Northwest Medical Society of Philadelphia, November 2, 1903.

Increased nasopharyngeal secretion. Saline purgatives, bromides to produce sleep and phenacetin for the pain and fever, were administered. Jan. 13. Rested badly during the night, slept but little, dreaming and awaking with starts; dull pain in the ear constant. During the day pain had subsided, patient resting fairly well; only a feeling of discomfort in the ear. Temperature 103.4° F. No bulging of the tympanic membrane, redness lessened, coryza unchanged, general aching throughout the whole body. Symptoms indicated influenza; this, however, proved incorrect. Jan. 14. Pain in the ear recurred in the night, increasing in intensity; chilliness and flushing alternating; general restlessness. Temperature taken by himself during the day at irregular intervals, varied from 103 to 105° F. Headache worse in the left half of the head, continued coryza. The tympanic membrane was then injected and bulging. I incised the drum and much fluid escaped. In ten minutes all pain had ceased and he felt perfectly comfortable. A small gauze dressing was applied. The discharge was so great as to wet the dressing in three hours. I was called back and applied a large dressing. When I left him at 11 P. M. the temperature had dropped to 100° F.; the patient was comfortable and thought he would sleep. At 3 A.M., however, he was awakened with pain in the right side of the chest. This increased during the remainder of the night and forenoon. Dr. A. A. Stevens was called and diagnosed croupous pneumonia. Dr. Stevens took charge of the medical treatment. The highest temperature after the paracentesis was 104.6° F. The decline was by lysis from 103.8° F. at 8 P.M. of Jan. 18, to 98 at noon of Jan. 20 and varied after that time from 97.8° to 99.2° F. until Jan. 30, when convalescence was fully established.

The discharge from the ear continued throughout the course of the pneumonia; being greatest during the height of the pneumonia and gradually lessening as the pneumonic manifestations subsided. After the lung had cleared up and the temperature remained normal, the discharge ceased and in three days the perforation in the tympanic membrane healed. I examined the ear again recently and found the drum normal in appearance, unrestricted in mobility. At times, in cold, windy weather, there is slight pain in the previously affected ear, but no more so than in others who have never had otitis media.

I regret no bacteriological examination was made. I cannot, therefore, positively assert that it was a pneumococcic otitis. But the course of the two conditions were simultaneous, the height of one corresponding to that of the other, and both subsiding together leaves no doubt in my mind that there was a simultaneous infection of the middle ear and lungs, and by the same cause. The ear symptoms developing first and overshadowing those of the lung.

HEPATECTOMY FOR TUBERCULOMA OF THE LIVER.*

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.ENG.,
OF CINCINNATI, OHIO;
PROFESSOR OF PRINCIPLES OF SURGERY AND CLINICAL SURGERY, MEDICAL COLLEGE OF OHIO; UNIVERSITY OF CINCINNATI.

The operative treatment of surgical affections of the liver has been the outgrowth of the past two decades. Although abscesses and cystic growths had long been treated by surgical intervention, the surgery of solid neoplasms necessitating resection of the liver, was not undertaken until the experiments of Tillmans, Ponfick, Gluck and Cecherilli had demonstrated the compatibility of even large resections with continuance of function, and the further demonstration of the rapid degeneration of the liver tissue.

Since Lins in 1886, and Langenbuch in 1887 removed large movable portions of a corset liver, many operations have been performed upon this vascular gland. The most complete compilation of cases thus far published is that prepared for Keen by Spencer, Cushing and Downes.[1] The cases of resections numbered 76 in 1889. Cases have since been recorded by Elliott,[2] Beck,[3] Kocher,[4] Fillipini,[5] Tricomi,[6] Langer,[7] Legueu,[8] and Nauman.[9]

In gleaning the literature of this subject it becomes at once apparent that it is difficult to make a distinction for statistical purposes between cases in which the liver tissue is merely incised for the removal of an enucleable growth, and those in which a considerable portion of the liver tissue wherein the neoplasm is imbedded, is the essential feature of the operation. Keen has carefully attempted to exclude cases of hepatotomy, including in his table only cases in which resection was done. According to this table the mortality of all liver resections is 15 per cent. According to the statistics of Terrier[10] 10 out of 42 cases died from the operation, a mortality of 19.23 per cent. An analysis of the last 17 cases of Spencer and Cushing's table will show that resection for carcinoma has a mortality of 50 per cent. Of these cases recorded only three entirely recovered from the operation; one died on the third day, one after six weeks and one after three months.

Doubtless a number of cases reported as recoveries after resection for carcinoma have in reality been cases of gumma. Such, for example, was the fact in the celebrated case of Lücke, in which he removed the left lobe of the liver. Madelung[11] subsequently showed the tumor to be a syphilitic gumma. This perhaps accounts for the permanence of the cure. Elliott states that of nine cases operated on for syphilitic tumor only two died. According to this writer in 12 cases of malignant disease recently resected, eight for carcinoma and four for sarcoma, one died from the operation and two were known to have no recurrence at the end of two years. One of these is the case of Lücke to which allusion already has been made. The case of Fillipini re-

* Read before the Southern Surgical and Gynecological Association, December, 1903.

sected for adenoma had a recurrence after three and one-half years. From personal communications from Keen, Elliott, Monks and Beck, I am enabled to report that there was a recurrence in each. Including the cases of Beck and Kocher, one death and one recovery and the one recorded below, supposed primarily to be cancerous, there are 16 cases with three deaths.

In all of these cases the growth was supposed to be primary, as it of necessity must be if at all operable, and in the form of a single tumor. That this is not always possible will be shown in the following case. If one considers the fatality of solid tumors of the liver, excluding gummata, the statistics presented, although far from promising for the permanence of the recovery, may still justify resections for solid tumors of the liver limited in number and position. On resection of the liver for solitary tuberculoma, I have been unable to find any literature. Believing that in a field of surgery where justification of operative interference and the technical methods are still somewhat debatable, every case, especially if unfavorable in its result, should be recorded. I beg to submit the following report:

Male; aged thirty-six years. First examination October 18, 1903. Admitted to hospital October 21, 1903. Both parents are living and in good health. Brothers and sisters all living. History as to lues negative. Ten years before onset of present malady had left testicle removed for tuberculosis. Since then the patient has been in excellent health until four months ago. He has been married six years and has one child, one year old and healthy. There is no history of miscarriage. In November of 1902 the patient once consulted me for a pain in the right loin which proved to be an ordinary lumbago. During the past four months he experienced a sense of weight and then of pain in the pit of the stomach. This he believed to be some form of dyspepsia. Although spare of habit, the patient has noticed some little loss in weight. He has not vomited during his illness nor has he been nauseated at any time. In the past two months he noticed a tumor growing under the tip of the sternum.

Physical examination.—Man of sallow hue of skin, but without traces of lues. Weight 120 pounds. Heart and lungs normal. Urinalysis normal. On examining the abdomen, a tumor is at once seen in the epigastric region. It can readily be palpated through the thin abdominal wall. It is irregular in outline, its long axis corresponding to the border of the left lobe of the liver. Its short axis, which is about two inches long, has its upper end removed about two inches from the tip of the sternum. The tumor seems very mobile, as it moves very distinctly with respiration. The percussion note over the left tumor is distinctly dull; and the dulness is directly continuous with that over the liver. Below and to the left, the dulness is sharply defined against the tympanitic resonance of the stomach and intestines. Examination of the abdominal viscera including the rectum reveals nothing abnormal. An examination of the stomach by Dr. Ramsey showed it normal in motility and secretion.

Diagnosis.—Tumor of the liver, probably primary in character and of cancerous nature. This diagnosis was concurred in by Professors Osler, Hare and Forchheimer.

Operation October 23, 1903. Ether narcosis. An incision in the midline from the ensiform cartilage downward and about four inches in length at once revealed the tumor which was imbedded in the left lobe of the liver. The omentum was adherent to the free border and was secured and divided between double ligatures of fine silk. This accomplished, the pylorus and most of the stomach was carefully examined and found free from disease. No lymph nodes were found in the lesser or gastro omentum. What was felt as the tumor mass was now found to be the left lobe of the liver, hardened and nodular on its lower surface, but quite movable. Since the tumor appeared malignant and therefore unsuited for enucleation, I determined to remove it by resection if I could be reasonably certain of its being a solitary growth. To this end an oblique incision three inches in length was made to the right. All of the under and most of the diaphragmatic surfaces of the liver were thereby placed within touch. A second tumor was not felt.

By gentle traction the left lobe of the liver was brought into the abdominal wound. It was difficult to hold it, so I therefore concluded to follow the method successfuly adopted by Lücke and others in completing the operation in two sittings. To this end two large, blunt-pointed bullet probes were passed at right angles through the thickness of the liver, an inch or more beneath the tumor mass, and an elastic tube thrown around the liver to form a pedicle. The lower part of the wound was closed in the usual way, the upper part lightly packed with gauze. The patient left the operating table in excellent condition; pulse 82.

October 24. During the morning the dressings became saturated with blood. When they were removed it was found that a quite profuse bleeding was going on. There was great thirst; pulse 120. Under ether anesthesia the wound was examined and the source of hemorrhage sought. It was found that the elastic tourniquet had forced the skewers through the liver tissue, thus producing slight lacerations from which the hemorrhage came. The band was therefore removed and by means of one of the skewers a very heavy ligature was made to take its place. There was no further bleeding. With the thermocautery the left lobe was now cut away without the further loss of even a drop of blood.

During the first forty-eight hours after the operation the condition of the patient promised much. There then supervened a vomiting and hiccough which could not be controlled. From the third day the vomitus consisted chiefly of blood. There was neither pain nor abdominal distention indicative of peritoneal infection.

Death followed on the sixth day after operation, probably from necrosis of the gastric mucosa from retrograde thrombosis of the omental veins. A partial autopsy was made. Dr. Carl Hiller reports on this and on the nature of the tumor as follows: The excised piece of liver is cone shaped with the apex representing the extremity of the left lobe, and the base artificially produced by the incision with the thermocautery. This base measures 32 cm. in circumference, 9½ cm. in its longest and 8 cm. in its shortest diameter. The surface is smooth and unaltered except at one portion which when the liver was undisturbed in the abdomen was on the under surface close to the anterior sharp margin. Here there is a nodule of grayish-white color standing out in bold relief against the surrounding liver tissue, which is of a normal color and consistence. The nodule when a cut is made into it at right angles to the surface of the liver, presents an ovoid surface of firm consistence throughout and is sharply defined from the adjacent liver substance. This nodule measures on its cut surface 23 mm. in its shortest and 26 mm. in its longest diameter.

On examination after death the remaining portion of the liver showed that where the elastic band had compressed it, there was much discoloration. Other than the presence of a similar nodule half the size of the one already described, nothing abnormal could be detected. This nodule was in the right lobe on the upper surface of the liver close to the peritoneal reflection. With the exception of a slight inflammation about the stump of the liver, nothing abnormal could be detected in the abdomen.

An examination of the specimens made from the nodule by the microscope reveals connective tissue in large amount. Both fully developed and forming connective tissues are found. The youngest connective tissue is represented by loosely packed spindle cells which lie by the side of cells with large vesicular nuclei. These are believed to be epithelioid cells derived from connective cells. Here and there, but not very frequently, can be noticed a giant cell with peripherally situated nuclei and a degenerated center. Blood vessels exist only as capillaries which are limited to the outer portions of the nodule. It is here that the nodule is most cellular, so that the appearance of granulation tissue is presented. Separating the granulation tissue from the most central portion of the nodule are more matured connective fibers, which at places are quite dense. The center of the nodule is made up of a homogeneous necrobiotic area of large extent, which contains here and there a few cellular elements.

The diagnosis of solitary tubercle was made, although the tubercle bacillus could not be demonstrated in the specially stained sections.

Remarks.—In connection with the case reported, I would direct attention to two questions, one involving that of diagnosis, the other that of the technic necessary to forestall hemorrhage.

The diagnosis before operation was that of primary hepatic tumor. This was made with the full knowledge of the great rarity of such tumors. Kehr in 600 laparotomies found only one of this nature. Of cancer not more than one in 64 is primary. Man[12] found 246 secondary and only four primary cancers. The most extensive manual and visual examination of the liver possible at the time of operation failed to reveal a second growth. Nevertheless the autopsy showed such a lesion in the right lobe of the liver, where it could not be felt intra-vitam. The very serious difficulties hampering the pathologist in coming to a conclusion as to the nature of the growth when diligent study of sections is made will show the difficulty of the operator in determining the nature of a solid growth, while the operation is in progress. At the time of the operation it was believed that the tumor herewith presented was a primary carcinoma. A more careful examination makes it almost certain that the case is one of large tuberculoma. Solitary tuberculous tumors of the liver, although described by pathologists, are exceedingly rare. I believe this to be the first case in which a resection of the liver was made for a tuberculous tumor.

In regard to the technic of hepatectomy, it may now be laid down as a rule that immediate closure of the abdominal wound is to be condemned. In the cases of Langenbuch and Wagner severe secondary hemorrhage followed this procedure. Langenbuch had the temerity to reopen the abdomen. Even when the intraperitoneal method of treating the wound is practised, a gauze tampon as used by many surgeons including Eiselsberg, Israel and Keen, ensures the safety of the peritoneum against contamination from bile and against concealed bleeding.

The extraperitoneal method adopted by me in the case reported has been followed according to Tricomi in about 37 per cent. of all hepatectomies. Of course, it is applicable only to cases where a pedicle can be formed. Following the method of Lücke, an elastic ligature was used and this was held in place by skewers. It did not prevent bleeding because of the cutting of the rubber constricting band. It does not seem to me, however, that the exitus in this case can justly be ascribed to the hemorrhage. As to the safest means of preventing this when the intraperitoneal method is to be followed, operators are still at great variance. The thermocautery has very many advocates but is considered unsafe by Kocher. Clean excision and careful ligation of the large veins with catgut, as done by Heidenhain, Keen and others, permit the reduction of the liver wound by approximating its peritoneal margins. The experiments of Kusmetzon and Penzky have shown that the tying of hepatic veins of transfixion sutures is, at least in animals, an easy method of arresting hemorrhage. This method, together with gauze packing for added safety, seems to me an ideal one where applicable. In two cases Kocher used pylorectomy clamps on each side of the mass to be removed, crushing through the liver tissue. The mass included between the forceps was removed with a knife with-

out much bleeding. The forceps were left in position forty-eight hours. In one of his cases, however, a fatal prolapse of the intestine occurred through the wound.

THE RELATIONSHIP EXISTING BETWEEN OPHTHALMOLOGY AND OTOLOGY AND DENTISTRY.*

BY FRANK ALLPORT, M.D.,

OF CHICAGO;

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLOGY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, ETC.

When requested to write something for this society upon the relations of odontology to ophthalmology and otology, I assumed that the invitation, was not so much an honor to me as the manifestation of a strong desire on the part of this society to be again addressed by some one possessing the name of Allport. Many gentlemen in the room this evening were my father's personal friends; some are here who did not know him. But whether knowing him as an associate and colleague or belonging to a newer generation which did not know him at all, whether trusting him and agreeing with him in his strong and undisguised views concerning dentistry and its destiny, or disagreeing with him and considering him overzealous or too enthusiastic, I am confident you must all unite with me in regarding him as one of the world's great dentists, and as a man whose honesty, integrity and purity of purpose can never be brought into question. I am sure it would gratify my father immensely if he could know that a dental society had invited his son (a physician) to address it upon the interdependence existing between Medicine and Dentistry. For those of you who knew my father, or have followed his life, know that he lived principally for one object, viz, to see dentistry acknowledged throughout the length and breadth of the civilized world as a legitimate specialty in medicine, even as ophthalmology or neurology is so considered.

To this end and in order to make the idea symmetrical, he believed that dental schools should have no existence except as post-graduate institutions, that those desiring to become dentists should first take a degree as a doctor of medicine, and should then pass into a dental school to receive special instruction in his chosen profession. He advocated and secured the establishment of dental chairs in medical colleges; he was largely instrumental in the establishment of a dental section in the American Medical Association, and in the International Medical Congress. Besides these important labors, he was a practical dentist who had few equals and, I believe, no superiors. He was a friend of good and conscientious work wherever found, and was always a kindly and honest advisor to young, struggling and ambitious colleagues; he established fees for dental services that have been a lasting benefit to dentists in Chicago and elsewhere; and I think you will all unite with me in saying that the benefits which he conferred upon dentistry are far-reaching and will never die.

I trust you will pardon this eulogy of my respected father, which some may regard as in poor taste, but the pleasant conference between this society and myself seemed a not inappropriate occasion for me to speak the thoughts which lay uppermost upon my mind concerning his life and work, and to pay a tribute to his memory, which I trust, nay believe, has not fallen upon unsympathetic ears.

It surely requires no strength of the imagination to assume a distinct connection between ophthalmology, otology and odontology. No portion of the body is a kingdom in itself, independent of other portions. Cardiac affections may permeate every nook and cranny of the human organism, and the same may be said of hepatic, spinal, uterine and other diseases which have their principal pathological centers in some particular section of the body. No argument is necessary to convince us that diseases of the teeth and mouth may produce pathological changes in the organs of sight and hearing, and possibly *vice versa*. We know it because we have seen it over and over again, and an article on this subject is only valuable as an effort to emphasize and reiterate well-known facts and to crystallize them into definite and tangible form, for, although these clinical data stand undisputed, it is much to be regretted that ophthalmologists and otologists are prone to neglect carelessly the prolific etiological influence of the mouth.

Diseases of the mouth may produce pathological changes in the eye or ear by one of two channels, by direct continuity of tissue, or by reflex irritation. We must not, however, lose sight of the fact that many diseases whose underlying cause has been ascribed to an elusive reflex phenomenon, have been shown to originate in an actual migration of infective microorganisms along the fibers of nerve tissue. Neither should we allow the pendulum to swing too far the other way in this age of doubt and materialism, to the elimination of *all* reflex pathological conditions, for it is surely difficult to harmonize the theory of septic infection with prompt disappearance of subjective and objective phenomena, upon the removal of the offending cause, such as a tooth, for instance. As illustrating the point, Milliken reports a case of healthy man who contracted two attacks of iritis: The first came on with the cutting of a wisdom tooth and disappeared upon the subsidence of the gum inflammation; the second after losing a filling in the third molar

* An address delivered before the Chicago Dental Society, December, 1903.

upon the same side as the affected eye, and was immediately relieved after the tooth was excavated, sterilized and filled. There was no apparent septic invasion of the iris, and the prompt disappearance of inflammation upon the removal of the irritating cause would seem to argue against the theory of septic migration.

As a still clearer instance of the actuality of reflex influence, Neuschüler, of Turin, reported a case in the *Recueil d'Ophthalmologie* for August, 1899, of a man who noticed that after prolonged use of the eyes he suffered from an intense pain in the orbit which, later would invariably spread to the teeth and become so severe as to necessitate cessation of eye work; a correction of his refractive error by glasses relieved all his symptoms. In the *Annals of Ophthalmology and Otology* for October, 1895, Foucher, of Montreal, reports the case of a man fifty years of age, who had a decayed, aching and broken molar tooth. He developed a keratoscleritis and conjunctivitis, together with herpetic eruptions on the cornea, and a little above the eyebrow along the sensitive branches of the ascending frontal nerve. The tooth was extracted and permanent relief promptly obtained. Foucher also reports another case of a woman age twenty-one years, who had an irritable wisdom tooth, accompained by great pain in the eye and optic neuritis, with total suppression of vision. The tooth was extracted and a speedy cure followed. Samuel Theobald, of Baltimore, reports a case in the *Medical Record* of Feb. 25, 1883, of a man, aged twenty-six years, who contracted a suppurative inflammation about the root of the left upper lateral incisor tooth, the pulp of which had been previously destroyed by a dentist. The tooth was decayed but not painful. The pupil of the left eye became dilated and paralysis of accommodation occurred. The tooth was extracted and the ocular affection was soon cured.

Theobald in the same issue reports a very remarkable history of a man thirty-five years of age, the crown of whose right upper lateral incisor being broken off, inflammation around the root and alveolar process followed. Both pupils speedily became immobile and paralysis of accommodation took place together with retraction of the lids of the right eye. His taste was impaired. The tooth was extracted and the morbid conditions were less severe, but a cure was delayed from time to time by root and alveolar inflammation of other teeth. Each time a tooth was extracted the ocular conditions improved but fresh exacerbations occurred as the inflammation was continued from one tooth to the other. A cure was not accomplished until all the diseased teeth had been extracted.

It certainly appears as if in this last case of Theobald's we may at least feel we have had a striking example of reflex ocular disease due to persistent irritation of a branch of the fifth nerve. The theory of cell migration seems hardly possible with a history of such frequently recurring ocular explosions, accompanied by complete cure upon a removal of the etiological factor. Sewell claims to have seen the development of a cataract after extracting a tooth, although one case of this nature hardly seems sufficient basis for an opinion. Neuschüler in the *Jahrbuch für Augenheilkunde* 1888, p. 403, reports a case of incorrect balance of the ocular muscles which appeared to act as an etiological factor of toothache, as the latter was cured by a correction of the muscular anomaly by the use of prisms. Knies claims to have occasionally cured nictitition by the removal of a painful tooth, and Gasselin makes similar assertions concerning supraorbital neuralgia. Amblyopia and amaurosis are quite frequently reported as caused by irritable teeth by Lardier, Gill, Metras, Samelsohn, Keyser and others, and Knies observes that when the symptoms appear without any other visible lesion, the connection may be taken for granted. The majority of dental reflex disturbances of an ocular nature, however, seem to be those of diminished or suspended accommodation, and Schmidt in the *Archives of Ophthalmology*, Vol. XIX, p. 107, has noticed 73 cases of weakened accommodation out of 92 recorded cases of ocular disturbance with dental etiology, and claims that such reflex phenomena are especially frequent in young people. It is indeed a matter of common observation that many of the eye and ear diseases of infancy and childhood, notably phlyctenular keratitis and conjunctivitis and acute otitis, are apparently caused by teething and defective teeth, frequently accentuated by the entire absence of parental supervision over the mouth and first teeth of growing children.

Who shall gainsay the theory that one reason why children are so prone to eye and ear affections is, not only the occurrence of exanthematous and children's diseases, but also the presence of the physiological and pathological condition to which reference has just been made? It might indeed be difficult to prove that the discouraging and prolonged interstitial keratitis so often accompany the pegged, softened, serrated and sensitive teeth of Hutchinson, are dependent entirely upon the underlying syphilitic taint. I think it is not at all impossible that an etiological factor might also be found in the characteristically diseased teeth, almost if not quite invariably present in these cases, and one reason why interstitial keratitis of this nature is so stubborn and prolonged in its clinical history may be found in the equally and coincidentally stubborn and prolonged morbid condition of the teeth. Schmidt is of the opinion that many morbid ocular conditions of dental origin are dependent upon a nervous relaxation of the ocular blood-vessel walls, thus allowing an abnormal amount of blood to remain in the eye and producing various paretic and other conditions, such as sluggish pupils, loss and spasm of accommodation, congestion of the retina, uveal tract and optic nerve, or even glaucoma, etc. Kneiss thinks that when loss of accommodation occurs during a toothache it probably results simply from the lack of vigorous innervation due

to intense suffering. He also thinks that muscular insufficiency and diplopia, which are occasionally observed, may also be explained as paresis due to enfeebled innervation, a theory which can be readily understood as an easy and rational explanation of some at least of the clinical phenomena.

We have all seen a severe toothache produce neuralgia, redness of the eye and excessive weeping, but we must not be too quick to conclude that the tooth is an etiological factor, not indeed, until the neuralgia and ocular conditions promptly disappear upon cure of the dental disease. The outlines of cause and effect, however, are sometimes beautifully demonstrated, as for example in an instance cited in 1885, by Hutchinson who observed a marked case of lagophthalmos from spasm of the levator palpebræ superioris, which promptly ceased upon the removal of an aching tooth, and Vossius in the *Archives für Ophthalmologie,* Vol. 33, mentions cases of exophthalmos developing from serious infiltration of the orbital tissue, which disappeared rapidly after extracting a diseased tooth. Instances of this nature have also been observed by Burnett in 1885 and Pagenstetcher in 1884, and Dimmer in the *Wiener medicinische Wochenschrift* for 1883, p. 299, claims to have seen metastatic choroiditis produced by the reflex irritation of extracting a tooth. Again referring to Kneiss, he notes that pain in the upper teeth on the same side as the affected eye is a frequent symptom of the so-called ciliary pains of keratitis, but particularly of iritis and cyclitis. Less frequently there is pain in the teeth of the lower jaw on the same side, and still less frequently in those of the other side; these are cases of irradiation of pain to adjacent nerve twigs.

Neuralgic toothache may be the prodromal sign of glaucoma. It must not be forgotten that the same general nervous supply extends both to the teeth and the eye, not only through the medium of the fifth pair of nerves, but also through the sympathetic system, and it is not difficult therefore to see how amblyopia, amaurosis, iritis, keratitis, conjunctivitis, strabismus, cycloplegia, etc., may be produced by diseased teeth of the upper, and even of the lower jaw, and also by poorly and improperly adjusted sets of artificial dentures, and malposition of the wisdom teeth.

While diseases of the ear of reflex origin dependent upon mouth diseases are not so well cut and clearly defined and recognized as ocular abnormalities, still they constitute a potential factor in aural histories, and must never be eliminated by one who makes careful examinations of his cases, for it is possible from time to time to find in the mouth the neglected and possibly unsuspected cause of some aural disease. I have used the word "unsuspected" but would not have it interpreted in its broadest sense, as I am personally exceedingly sceptical of the probable existence of an absolutely quiescent etiological condition. I regard it as very improbable that a diseased mouth will cause reflex or eye disturbances without the existence of some palpable morbid oral condition manifested both subjectively to the patient and objectively to the physician. This to my mind is the cheerful side of the otherwise mysterious and unfathomable history of reflex power. Without this probability the position of the careful diagnostician must oftentimes be wellnigh without hope, and attended by a helpless groping about in the Egyptian darkness of hidden and unknowable reflex pathology. In other words, if a diseased tooth is producing reflex eye or ear disturbances, I believe it will ache, sometimes more, sometimes less, sometimes being practically quiescent, but ache, and that a careful examination of the patient will disclose this fact, and clearly demonstrate its position as a source of disease. Therefore when I use the word "unsuspected," I mean "unsuspected" by the patient, for even though he has had a toothache or an otherwise known mouth disease, he does not associate it with his eye or ear disease because, like Kipling's "Vampire," he "does not understand," or "unsuspected" by the physician, because he is careless in his examination and diagnosis, or indisposed to attach much importance to oral diseases. The same pathological conditions of the mouth which will produce reflex eye diseases, and to which reference has already been made, will also cause reflex aural affections, and reversely, ear diseases may produce intolerable toothache. The terminal distribution in and about the mouth of the sensory and motor branches of the sensitive trigeminous and its associates with the great sympathetic, connects the teeth with the entire aural organism, and explains many of the reflex disturbances developing from the oral cavity.

The range of ear diseases produced in this way is much more limited than is the case with eye diseases, owing probably to the fact that there are fewer affections of the ear than of the eye, and also because the eye is more sensitive and susceptible to nervous conditions than the ear. Such aural affections are principally myringitis, earaches, sensitiveness of the ear canal, hyperæsthesia of hearing, deafness, furuncles and eczema of the ear canals, especially in children of a tuberculous or strumous diathesis, etc. The frequent occurrence of such aural affections, especially otalgia, with the teething of children, and its almost immediate relief by lancing of the gums, is of such common observation as to excite no comment. In lancing the gums under such circumstances, the incision should be deep so that the tooth may be absolutely liberated, for the pressure between the gum and the tooth crown is not the essential etiological factor, but the pressure at the root ends on the branches of the fifth cranial nerve, when the trouble is in the upper jaw, or on the inferior branch when in the lower jaw.

I have no doubt that careful examination of patients, both young and old, with such etiological factors in mind, would disclose the cause of many aural affections. Baldwin, in the *Journal of the American Medical Association* for Jan. 31,

1903, records seven cases of earache with no evident cause but exposed tooth pulp, all of which yielded promptly to treatment of the teeth, two cases of severe earache during the regulation of cuspid teeth due to tension of the regulating apparatus; many cases of pain in the ear during the filling of teeth, especially molars; one case of earache due to sensitive dentine; twelve cases due to deciduous teeth blocking advancing molars; eleven cases of tinnitus aurium, much if not entirely relieved by treatment of the teeth. As can be readily imagined, it is sometimes extremely difficult to draw the line between eye and ear diseases which are reflex in their nature, and those which are produced by actual cell migration or by inflammation spreading by direct continuity of tissue. Some conditions may be easily classified while others must needs live so near to the borderland that their nativity is shrouded in pathological mystery. It must not be forgotten that the periostal lining of the orbit is continuous with the alveolar border of the upper jaw, and almost so with that of the lower jaw as well. The mucous membrane of the mouth is directly continuous with that of the conjunctiva, Eustachian tube and middle ear. Occasionally the apices of the roots of some of the upper teeth extend directly into the antrum of Highmore, and from this situation disease frequently reaches the orbit through a thin partition of bone. The angular artery and certain veins run almost directly from one region to the other.

Personally, I am exceedingly skeptical of those cases of so-called reflex ocular or aural disease of oral origin, where intense inflammatory or purulent conditions are present in the eye or ear. I believe such diseases to be produced either by the migration of infectious microorganisms, through the nervous or vascular structures, or else by the extension of inflammation by periosteal or mucous tissue. Arnold Knapp reports a case in the *Archives of Ophthalmology* for May, 1902, of a patient, sixteen years of age, whose right canine and two upper incisor teeth had been filled at the line of the gums. Alveolar abscess followed in three days, the right side of the face became swollen and the right eye closed. Five days later the gum in front of the canine tooth opened and pus was discharged. The swelling diminished and the lids opened. The right eye was blind, the optic nerve white, the pupil was dilated and immovable. A firm flat swelling appeared in the orbit. A purulent fistula was established in the canine fossa. A probe could be passed upward and forward under the periosteum and exposed a roughened bone detached. The eye remained blind. F. W. Marlow, of Syracuse, N. Y., reports a case in the *Annals of Ophthalmology* for Jan., 1897, of a young woman, aged twenty-five years, who had an alveolar abscess of the first bicuspid of the left upper jaw which was opened and cured. It proceeded from an infected root canal. She developed pain in the ear and optic neuritis with great blurring of vision and subsequently entirely recovered. Dagilaiski, of Novgorod, reports a case in the *Klinisches Monatsblatt für Augenheilkunde* for July, 1899, of a boy seven years of age who suffered severely from alveolar abscess in the upper jaw accompanied with much swelling of the cheek and face, particularly about the eye. Pus was pressed from the diseased and carious tooth socket, which was that of the first upper left molar. The tooth was extracted and the antrum cleaned, during which process much pus escaped from the nose. A cure followed and Dagilaiski believes that the infection spread from the tooth along the periosteum of the upper jaw. Braunschweig has observed two cases of iritis with pus in the anterior chamber as a result of diseased teeth, and Swanzy has seen cases of orbital cellulitis following inflammatory conditions in and around the teeth. It is a matter of common observation that erupting misplaced and diseased wisdom teeth often cause tonsilitis, which is followed by inflammatory and painful ear affections of a purulent or non-purulent character, probably produced by the close connection between the tonsillar region and the Eustachian tube.

But it is unnecessary to further rehearse cases and illustrations; the facts are well known to us all, and I presume there is not a practitioner present who could not substantiate all I have said, with citations from his private practice. The purpose of this paper is not to furnish new thoughts, but to emphasize old ones, for a long personal experience in ophthalmology and otology, with an inherited tendency to exaggerate the importance of odontology, leads me to the belief that proper respect is not yielded to the undoubted connection between your specialty and mine. I would particularly urge eye and ear surgeons to carefully examine the mouth as a matter of routine, not forgetting to closely scrutinize crown work and plates, remembering that crowns are often injudiciously placed, that artificial teeth sometimes do not fit, and are even occasionally fitted over broken roots, which can hardly fail to produce irritation, reflex and otherwise, that may account for physical ailments unsuspected by an inexact diagnostician.

Following the advice of Baldwin, I would urge the establishment in all free dispensaries of a dental department, where proper oral therapeutics might be administered and where cases of the nature outlined in this article, could be promptly referred and correctly treated, and it is gratifying to note that at a recent meeting of the National Dental Association, held at Asheville, N. C., the following resolution was unanimously adopted:

Resolved: That it is the sense of the National Dental Association, that each medical college in the United States should include in its curriculum a lectureship on oral hygiene, prophylaxis, and dental pathology.

This resolution should be warmly endorsed by the medical profession and especially by those who are influential in framing the policies of medical instruction, for the active influence of oral physiology or pathology upon bodily health

and disease can no longer be brought into question.

It is also gratifying to know that the municipality of Strasburg has recently voted to build an $80,000 dental hospital for school children. Every pupil in the schools is to be submitted to a dental examination on entering and twice during school time until the age of thirteen. The municipality has come to the conclusion that a large proportion of the ills of young people are due to bad teeth and lack of proper dental attendance. Now, while it may not be possible to erect hospitals for this laudable purpose in all cities, it is both possible and feasible for boards of education and boards of health to appoint dentists who may quickly, yet efficiently, examine the teeth and mouths of all public school children once a year. Those suffering from oral abnormalities can receive warning cards to be given to their parents, notifying them of such conditions and advising them to have their children's mouths cared for either at some office or free dispensary. In this way the health of the coming generation would be much improved and a truly incalculable benefit conferred upon mankind. Years ago I devised a plan of this nature for the examination of school children's eyes and ears by school teachers, which has proven most successful and is now being used with gratifying results all over the United States, and even in many cities in Europe and Asia. If the plan is successful in searching for eye and ear defects, why may it not be equally efficient in detecting those of an oral character? I believe it may, and that it only needs the combined action of a united profession to place it in operation.

A HISTORICAL SKETCH OF SOME OF THE SO-CALLED CURES FOR CONSUMPTION: WITH A FEW NOTES ON LATER-DAY TREATMENT.

BY J. EDWARD STUBBERT, M.D.,
OF NEW YORK.

(Continued from Page 693.)

Maragliano* reports 130 patients treated with antitoxin serum, which is obtained in a manner similar to that of antitubercle serum. Of these "36 were clinically cured, including 17 with fever and destructive processes, with a cavity in three; 58 were improved, and the disease remained stationary in 31. In the remaining five the disease progressed. None of the advanced cases treated in the Institute were cured."†

In studying the results given by this form of treatment, the question arises whether there is any specific action in the specially prepared serum, or whether the ordinary serum obtained from any healthy animal, such as the horse or goat, would not produce an equally good effect. When we consider the pathology of the tuberculous deposit, remembering that, in the interior of the tubercles, the circulatory and lymph channels are excluded, it must be concluded that sera and tuberculins can have no direct effect upon the bacillus, but that the result must be obtained by an improved nutrition and increased resistance of the tissues surrounding the diseased area. Tuberculin and its modifications, as well as antitubercle serum, are still used by a small number of observers, and good results are from time to time reported. Among the modifications of the tuberculin of Koch and similar preparations, we need but mention: Kleb's tuberculocidin and antiphthisin, tuberculinum purifactum, water extrace of tubercle bacilli (Von Ruck), Maragliano serum, antiphthisic serum T. R., tuberculol, oxytuberculin, and U. S. antitubercle serum.

It is generally admitted that all these preparations are of use only in the early and incipient stages before any pyogenic bacteria have added the complication of septic poisoning, a time when it is also possible to check the disease with many other means at our disposal. A study of the reported results is interesting as indicating the class of cases in which tuberculin is of greatest service. Langenbeck and Wolff, Goetsch, Krause, Heron, Denison, Trudeau, and Von Ruck have reported their percentage of cures. They vary from 32 per cent of apparently cured cases, treated in various stages of the disease, to 83 per cent of those treated in the incipient stage only. Trudeau, with 24 cases, and Goetsch, with 175 cases, treated in the incipient stage only, report as apparently cured 83.0 per cent. and 71.0 per cent. respectively. In contrast, the percentages of those who did not limit the use of tuberculin to the incipient stage, average 38.6 per cent. Results in all the cases reported by the above writers show that of 416 patients treated, the average percentage of apparently cured cases is 51.73 per cent. Others who have used tuberculin, either as a therapeutical or diagnostic agent, are Koch, Douglas, Powell, Osler, Fraenkel, McCall Anderson, Eric France, C. T. Williams, Pottenger and Cornick. "Opinions differ greatly as to its value in treatment, less so as to its diagnostic use."*

A most dreaded condition in pulmonary tuberculosis is the occurrence of mixed infection causing a septic poisoning, as indicated by a high, spiked temperature curve, profuse sweating, rapid emaciation and depression of the patient, gastric disturbance and an excessive expectoration of sputum, muco-purulent or purulent in character, containing besides tubercle bacilli large numbers of streptococci, staphylococci, and sometimes diplococci. When the streptococcus predominates, a most satisfactory result is generally obtained from the use of antistreptococcic serum, 10 c.c. repeated every second or third day for two or three injections, if necessary. Often a single injection or 10 c.c. of the serum suffices. A drop in the temperature is immediately noted, sweats cease, there is less cough and expectoration, the nutrition improves, and the patient gradually

* Journal American Medical Association, Sept. 7, 1901.
† Progressive Medicine, Sept., 1902.

* Progressive Medicine, Sept., 1902.

loses the hectic flush. Examination of the sputum shows the streptococci to have disappeared entirely or greatly diminished in number. Throughout the course of treatment, the injection of antistreptococcic serum should be repeated as often as those germs reappear in the sputum. Their presence may be presaged by a return of temperature, sweating, and loss of appetite, leading to a bacteriological examination, which should be made at regular intervals in order that the reappearance of the pyogenic coccus may be met at once by full doses of the antistreptococcic serum.

Recognizing the staphylococcus as being frequently associated with the streptococcus in the mixed infections of tuberculosis, efforts have been made to obtain an efficient antistaphylococcic serum. Last year in France a combination product of both cocci was manufactured and a sample sent to this country. That sent to the writer was damaged in transit, so no accurate data were obtained. The reports from its use in France, however, are not as encouraging as we hoped, but the same investigators are still experimenting along this line.

Under the head of electricity we may consider not only the direct effects of the static and faradic forms, but also the active and powerful rays emanating from an electrical source. In static electricity, administered to a patient on an insulated platform, we possess a valuable adjuvant. In weakened and debilitated persons, as well as those of more robust temperament, its administration as a tonic should not be neglected. Giving the patient the positive electrode, the tonic effect is obtained. Cellular activity is increased, the gastric function is improved, and the absorption of both nourishment and drugs promoted. The latter effect is conspicuous in anemic persons, in whom the administration of iron together with the application of static electricity gives quicker and more decided results than when the electricity is not used. This fact was made clear to me by subjecting persons, who had previously been taking iron without the desired effect, to the static current and breeze, and noting a rapid improvement in the anemic condition and general health. In patients of neurotic tendencies the sedative effect of the negative pole is desired, which is soothing and productive of peaceful slumber.

The rays from an arc light, when concentrated upon the chest by means of powerful lenses, are supposed to possess a penetrative power intense enough to react on deep-seated tubercle bacilli, attenuating or even destroying them and, at the same time, restoring the tissue about the tuberculous focus to a more healthful condition. If it can be determined beyond a doubt that light in its various forms is so efficacious, we will have, theoretically, the ideal treatment for tuberculosis. Inhalations, injections, both intravenously and subcutaneously, and the administration of certain drugs are no doubt useful, but they do not penetrate tuberculous deposits because of their non-vascularity. Now, if a penetrating light is a germicide, might we not rationally expect a destruction of bacilli *in situ?* This accomplished, the disease should be limited to such an extent that general treatment, along the lines indicated at the present day, should permanently arrest the tuberculous condition. However, some observers believe that "X-ray stimulation does not kill tubercle bacilli, but stimulates them to excessive overgrowth and only affects them adversely by attenuation from overgrowth."*

As evidence of the germicidal action of the light rays, the writer recalls a case of empyema in which there was reaction of eight ribs resulting in a permanent fistula. The patient wore a silver tube fitted with a valve to prevent ingress of air after compression had arrested the activity of the tuberculous process in the lung. The discharge from the fistula contained tubercle bacilli and pus cells. He was exposed daily, for fifteen minutes, to the direct rays of an arc light with the result that, at the end of two months, the bacilli had disappeared from the discharge. This treatment was continued for six months, during which time no bacilli were found either in the sputum or the discharge, but two months thereafter microscopic examination revealed a few bacilli in the discharge.

Exposure of the bared chest to sunlight has been practised, but it has been demonstrated that the arc light, placed eight to ten inches from the chest wall, has slightly more power than the sunlight when it reaches the earth on the hottest summer day. The light is intensified by placing behind it a powerful reflector.

Currents of high frequency have been experimented with by Margazalli, Maragliano† and Chisholm Williams.‡ They agree that good results are obtained in that there is an improvement of all symptoms, and that bacilli are decreased in number after an initial large increase. The effects of high frequency current are: (1) Increase of pulse-rate during the actual applications of the currents, especially in consumptives; (2) increase of respirations which, after a time, become deeper in character; (3) increase of the power of digestion; (4) on the tubercle bacilli, attenuating their virulence by stimulating them to excessive overgrowth; (5) increased action of the kidneys. In his experiments on animals and men, D'Arsonval observed that the output of CO_2 was raised from 17 liters to 37 per hour, and the production of heat was increased from 79 calories to 127 per hour.

Recent investigations by G. Kaiser (*Wiener klin. Wochensch.*, 1902, No. 7) have caused him to ascribe to the action of the blue light a remarkable power of penetration, together with a depressing influence on bacilli.

The Finsen light, obtained from an arc light with the use of reflectors and lenses, has been exploited as a cure for malignant diseases, super-

* Forbes and Wolfenden, Arch Roentgen Rays, Aug., 1900.
† Journal American Medical Association, August, 1901.
‡ Philadelphia Medical Journal, November, 1901.

ficially situated, as well as lupus and pulmonary diseases. The original apparatus of Finsen has been modified in London. The results attained by its use do not seem to exceed or even equal those produced by the X-ray, nor does the Finsen light seem to be as powerful. It takes about twelve months to cure a case of lupus, while with the X-rays a similar result may be obtained in from six to twelve weeks. This may be due to the fact that the rays of shortest wave length, coming from the violet end of the spectrum, produce a chemic action. These rays are obtained more freely and in greater quantity from the X-ray tube than from an arc light, and, therefore, in the X-rays we possess a far more potent therapeutical light than the Finsen rays. Whatever the action of the X-rays may be on tubercle bacilli, it has given decided clinical results in some cases. In one case, treated by the writer, decided improvement was obtained. The patient was a male, forty years of age, with extensive areas of tuberculous consolidation and softening in the upper portion of both lungs. A large cavity was present on the left side and below, extending to the lower border of the upper lobe, was an area in which softening was rapidly progressing. On the right side there was a similar condition existent in both the upper and middle lobes, except that the cavity was smaller. A fatal prognosis had been given, and the patient told to go home and give up treatment. At his own request (he being a physician), the X-ray was applied four months, with the following results:

The evening temperature fell from 103° to 100° F., expectoration decreased about 60 per cent., the number of pus cocci were markedly decreased, and the sputum became more mucoid in character. No beneficial effects were observed upon the tubercle bacilli; on the contrary they seemed more prominent in the microscopic field, thus bearing out the statement heretofore made that the first effect of the X-ray upon tubercle bacilli is to promote overgrowth. The patient's weight increased one or two pounds and then remained stationary. The cavity on the left side became somewhat smaller and the area of softening below it was replaced by comparatively dense fibroid tissue. The small cavity on the right was partially obliterated, and a portion of the softened area disappeared entirely while that remaining was replaced by fibroid tissue. An interesting clinical feature in this case was that, proportionately with the increase of fibrosis, dyspnea increased. The patient was finally sent to Arizona to spend the winter months, and the partial arrestment of the disease has continued. This case is quoted only as a matter of interest, with the statement that one case does not make history.

The action of the X-rays on the skin is noted in three degrees: (1) Tanning, (2) blistering, and (3) burning. The first is unavoidable and harmless; the second occurs very frequently and, by some authorities, is considered necessary to attain the best results; and the third is sometimes unavoidable, but never dangerous. The latter, however, should be avoided whenever possible, both in the interest of the patient and the physician. The writer believes that the action of the X-rays encourages a breaking down and absorption of the tuberculous deposits at the same time that an increased activity of the healthy tissue surrounding the diseased area causes a protective fibrosis. Overstimulation with the X-ray may produce an undesirable extensive breaking down, which produces a septic condition, indicated by a rise in temperature, and, if persisted in, may hasten the death of the patient. Therefore, it must be remembered that, even without burning, it is possible to do the patient great harm. The temperature should be watched in all cases under X-ray treatment, as well as the condition of the skin. The absorption of ptomains from small areas of diseased tissue, when broken down by the X-rays, is of no importance, but when the areas thus acted upon are at all extensive, the patient may readily be overwhelmed by sepsis and too rapid absorption.

Upper Air Passages.—It will be well to note here the importance of a thorough examination of the upper air passages in all cases of pulmonary tuberculosis. As an aid to treatment, it is absolutely necessary to remove all obstructions to proper respiratory movement from the nasal passages, naso-pharynx, pharynx and larynx. Turbinal hypertrophies, septal spurs, polypi, adenoids, enlarged faucial and lingual tonsils should be removed. Chronic congestion or infiltration of the arytenoids, if discovered early, may be easily cured by prompt local treatment. Statistics show that not less than 25 per cent. of persons suffering from pulmonary tuberculosis have more or less involvement of the larynx and nasopharynx. Of this number 38 per cent. present congestion or infiltration of the arytenoid cartilages, interarytenoid space, ventricular bands or vocal cords; 32 per cent. show ulceration in one or more of these places, most frequently on the cords or interarytenoid space; 30 per cent. have some abnormal conditions of the nasopharynx. I wish to emphasize this point because frequently in the consulting room, it has come under my personal notice that physicians of high standing have permitted such conditions to escape their observation.

Intravenous Injections.—In the hope of more surely reaching the affected areas in the lung, the intravenous injection of antiseptics has been proposed. Subcutaneous injections have also been made. The drugs thus used are formic aldehyde, hetol, cinnamate of soda, and cacodylate of soda. Landener's treatment of intravenous injections of sodium cinnamate has been employed by other experimenters, with a wide diversity of opinion as to the results. Albert Mann* believes a leucocytosis is set up, which, together with an active aseptic inflammation about the diseased area, replacing an inactive septic one, results in

* Philadelphia Medical Journal, March, 1902.

rapid cicatrization. Henssel* reports on 60 cases thus treated. He believes it to promote cicatrization and to be harmless to the patient. Gidionsen† uses hetol intravenously, but has found it of no greater advantage than the open air treatment, in fact, he considered it harmful as his cases lost weight and pyrexia was not improved. Max Wolff‡ reports negative results both in animals and in man from the use of hetol and igazol. Franck§ believes in the hetol treatment for early cases only. Onelli‖ ascribes the rapid improvement, shown within a month by a patient in an advanced stage of the disease, to intravenous injections of cacodylate of soda. Among others who have made use of injections of hetol are Krokiewicz¶ and Amrein.** The former thought they produced too marked a congestion and leucocytosis about the diseased area, and he, therefore, substituted the subcutaneous injection in smaller and more frequently repeated doses. He observed better results by the latter method, and when both methods were impracticable, he gave the drug in pill form. Amrein obtained no positive results.

The writer has used, intravenously, hetol, cacodylate of soda, and formaldehyde in 1 : 5,000 solution in a number of cases. The immediate results are generally unfortunate, a very serious chill and reaction occurring. The mental factor counts for so much in such cases that it is difficult to arrive at any definite conclusion as to the truthfulness of patients' statements, in which they professed to have experienced great increase of appetite and general well-being. The final results in all these cases showed nothing more striking than those to be expected from the infusion of the amount of normal salt solution used as the vehicle. This method of treatment, however, is still in an unsettled and experimental stage, and more complete reports with fuller details will be awaited with interest.

On the theory that phthisis may be due to disordered and diseased pulmonary innervation, May makes subcutaneous injections of silver nitrate in the neck, over the course of the vagus. The side selected for the injection is usually the one corresponding to the diseased lung, or both sides may be injected at the same time if both lungs are affected. The injection is made over or slightly behind the pulsating carotid artery, in the region of the neck, in a line between or near the angle of the jaw and the clavicle and nearer the latter than the former point. Four to seven minims of a 2½ per cent. solution of pure silver nitrate are injected, preceded by five minims of a 2½ per cent. solution of cocaine through the needle, which is not withdrawn until after the silver solution has been introduced. Larger doses have been used when indicated. The injection is followed by swelling, redness and pain. Cough and expectoration decrease, vomiting is lessened, sleep promoted, appetite and general strength increased, physical signs improve, fever diminishes, night-sweats are checked, and there is generally a gain in weight. Of forty cases reported, seven in the incipient stage were cured. Of 18 advanced cases, 5 died; two remain invalids; and 11 improved sufficiently to resume work. Of 15 far-advanced cases, 11 are dead, two are invalids and two are able to work. The writer made use of silver injections, but found that the patients strongly objected on account of the pain and discomfort.

Camphor, in one or two doses of two grains daily, has been given, and improvement in the physical signs as well as the subjective symptoms was noted.

The use of antiseptics in the form of inhalations has been considered another direct method of reaching the tuberculous process in the lung. Here, again, opinion differs as to their efficacy, some contending that, to possess germicidal power, the vapor or gas inhaled must of necessity be too irritating to the mucous membranes. On the other hand, we find favorable reports following their use, especially is this true of formic aldehyde. There are two methods of giving inhalations of formic aldehyde: (1) By use of an oranasal inhaler, which may be worn for many hours during the day and night; into this is dropped 30 minims of a 4 to 10 per cent. mixture of formalin, chloroform and rectified spirit, and renewed every two or three hours. (2) By generating the gas in a closed or partially closed room by means of a vaporizer, while the patient reclines and breathes the atmosphere of the apartment for two or three hours daily. Some advocates claim that it not only disinfects the room and its contents, but that it diminishes the cough and expectoration, reduces fever, and causes the tubercle bacilli to diminish in number, and sometimes to disappear. Of 22 cases treated with formaldehyde inhalations, at the same time enjoying the open air treatment, but no medication beyond a corrective for indigestion, reported by Muthu,* eight were completely cured; nine almost cured; one was slightly benefited, and the remaining four were indifferent.

What is known as "Alabone's Cure" consists of breathing the vapor produced by passing compressed air through tubes and flasks in such manner as to comminute the fluid to be used. In this manner formic aldehyde, menthol, eucalyptol, etc., are supposed to reach the air passages when inhaled. Creosote, ichthyol, and the oils of turpentine and tar as well as other volatile oils are used by inhalation. An effective germicidal action is ascribed to izal which has been given by mouth and as an intratracheal injection. The dose by mouth is two to ten minims given in capsule with five minims of cod-liver oil, once or twice daily. Campbell has made considerable use of it as an intratracheal

injection. As much as three ounces of fluid can be injected at one sitting—one part izal to ten of glycerin. While he reports no cases, he speaks of cures that have been effected.

In the treatment of pulmonary hemorrhage, there has been a decided change from the old style of general and local depletion. The ancient idea was to limit the inflammatory condition by bleeding just as they did in the more acute diseases. This idea gradually gave way to a conserving of strength and an endeavor to limit the amount of blood lost as far as possible. In this day we have not stopped at this, but have hoped by certain procedures to more efficiently control hemorrhage from the lungs. When Murphy announced the possibility of curing tuberculosis by injecting nitrogen gas into the pleural sac to immobilize and compress the lung, it occurred to the writer that it might also prove an ideal method to control hemorrhage. It was soon discovered, however, why it could not be so regarded. To be efficient there must be no pleuritic adhesions or bands, one must be able to definitely locate the point of hemorrhage, which is frequently impossible, and the lung must be capable of compression. The percentage of cases in which this treatment is available is necessarily so small as to render its use practically impossible.

Other means of compression are afforded by applying adhesive plaster bands or even a splint of plaster of Paris or some other material. Pleuritic effusions are at times allowed to remain in the chest in order to continue the pressure they exert on the lung.

Morphine is considered the most valuable drug in arresting hemoptysis. It slows the pulse, decreases blood pressure, relieves the desire to cough, and secures rest for the patient. It is best given in doses of $\frac{1}{8}$ to $\frac{1}{4}$ of a grain, combining the initial dose with $^1/_{150}$ to $^1/_{100}$ of a grain of atropine. The exact action of ergot was not formerly understood, but as it was known to control uterine hemorrhage it was thought capable of controlling hemoptysis. In this it seems we were mistaken. It is rarely as efficient as morphine, and is only indicated when the hemorrhage is supposed to be venous or from a small arteriole.

Other drugs are atropine, nitroglycerin, suprarenal extract or adrenalin, calcium chloride (grains 20 to 30 every four hours), and turpenol, drops three every two hours in milk. When the loss of blood is large, hypodermoclysis or intravenous infusion with normal salt solution, or transfusion, may be practised. It has been claimed by some writers that the atropine in the combination pills of atropine and morphine is responsible for the beneficial effects on hemorrhage, and, with this statement in mind, the writer experimented upon a number of cases with injections of atropine alone but failed to obtain any good results. It may be of interest to state here that the X-rays cause contraction of the arterioles. I am not prepared to claim any beneficial effect from them in hemoptysis, but I do know that in one case of uterine hemorrhage, in which bleeding occurred almost daily for three months following an operation, the application of X-rays effectually checked the hemorrhage, and the menstrual function became normal after seven exposures to the rays. An effect also noted in cancerous and other sanguineous discharges is that, under X-ray treatment, they decrease materially in quantity.

Experiments looking to the control of pulmonary hemorrhage have been made with subcutaneous injections of gelatin. Of those who have thus far made injections, the majority regard them as harmless, though there is no evidence that they are really useful. It is important that the gelatin used should be perfectly aseptic. The possible dangers of such injections are embolisms, necrosis and tetanus.

S. G. Bonney* believes that hemoptysis in consumption is less likely to occur at high altitude, but it may be more severe and cause greater shock than at sea level. In support of this statement, the writer recollects having seen patients at a moderately high altitude, who had had a number of hemorrhages at short intervals while living at sea level, in whom the hemorrhages disappeared entirely after reaching an altitude above 2,000 feet.

In hydrotherapy we possess an agent of considerable usefulness, both as a prophylactic and in the early stages of the disease. This does not mean that it is to be neglected in the more advanced stages. The primary idea is to produce a reaction of the skin and to promote cutaneous circulation. The degrees of application vary from bed baths and flagellations in those who are weak and confined to bed, to the needle spray, shower bath and spinal douches administered under a certain degree of pressure. It is important that the skin should be in such condition as to secure proper reaction. The surface should be warm or even moist. In the healthy, exercise immediately preceding the bath will be sufficient. In others a stay in the sweat-box, in which the temperature can be raised to any degree, is necessary, while for those confined to bed, wrapping tightly in blankets from head to feet will answer the purpose. The shock caused by dashing cold water on the warm body, followed by reddening of the skin, stimulates the patient, makes him less susceptible to draughts, induces more natural sleep, increases appetite, and produces a general feeling of well-being.

The value of urea in tuberculosis is, as yet, undetermined. Harper,* believing that gout and its allied diseases are antagonistic to the tuberculous process, and that those afflicted with the former diseases possess a natural antitoxin against the bacillus, supplies an excess of urea to those with tuberculous lesions by encouraging them to partake of certain foods rich in urea, namely, kidney, liver, and calves' or sheep's

* Medical News, October 1, 1901.

brains. In addition, he gives twenty grains of pure urea, dissolved in three ounces of water. Buck* reports good results in cases treated along this line.

The success of zomotherapy, or the treatment of tuberculosis by the ingestion of raw meat, probably depends upon the correctness of the above theory. It is stated that a somato-antitoxin exists in muscle plasma or serum, and is resistent to the tubercle bacillus. However, C. Frankel and G. Sobernheim† tested it in animals, and discarded it as unworthy of further experimentation.

Postural treatment has been proposed by Schenk‡ to promote hyperemia of the lungs. He elevates the foot of the bed twelve inches, and applies warmth to the chest by means of water coils, at the same time sponging the hands, feet, and abdomen with cold water. His theory is "That tendency to phthisis depends . . . upon a relative cardiac insufficiency, leading to a defective circulation through the lungs, and that those who suffer from pulmonary hyperemia, as a result of valvular disease, are comparatively immune."

Operative treatment, such as the aspiration of cavities followed by the injection of drugs, opening and draining of cavities, and the resection of diseased areas of the lung, have been attempted with no encouraging results. They may still be considered on trial. One great drawback to operative procedures is that those cases generally selected as suitable could, undoubtedly, receive as much benefit from less dangerous measures. Inunctions have not been neglected, the favorite drug used in this manner being iodine in one of its unstable forms.

In pyrexia, with so many other remedies at hand, it seems hardly advisable to administer antipyretics for the purpose of simply lowering the temperature. They may prove depressing while almost equally good results may be obtained from cold sponging and rest.

Night-sweats usually disappear on general improvement of the physical condition of the patient. If special measures are necessary, atropine will be found most useful. The mineral acids, tellurate of sodium ($^1/_{12}$ to $^1/_2$ grain daily) agaricin, may also be used, while bathing with cool water, alcohol or a weak solution of formalin may be of service. When the sweats are due to a septic condition in the lung, antiseptic inhalations are advisable, and serum for destruction of germs as well as intratracheal injections in cavity cases.

Cough can be sufficiently controlled by mental suggestion or by codeine, dionin, or heroin. In advanced cases, however, it may be necessary to resort to posture and massage of the chest.

Summary.—With our present knowledge and clinical experience in the treatment of this disease, diet, hygiene, and fresh air are universally accepted as the foundation of all scientific treatment, although it is equally acknowledged that, by themselves alone, they are not sufficient, but must be supplemented by symptomatic treatment in the way of antisepsis, tonics, and surgical interference when necessary. The probability is that within the next three years, we will see notable advances in immunization and the stimulating effect of light. In the meantime, the physician who would prescribe climate alone is equally culpable with him who would ignore climate, diet and hygiene in favor of medicinal or other treatment. The man who would justly earn the gratitude of his patients will be he who will prescribe a judicious, scientific combination of the two basic lines of treatment.

HYSTERIA AND ORGANIC DISEASE.

BY WILLIAM B. NOYES, M.D.,
OF NEW YORK;
ATTENDING NEUROLOGIST, DEMILT DISPENSARY; CONSULTING NEUROLOGIST, MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.,
AND
RICHARD C. NEWTON, M.D.,
OF MONTCLAIR, N. J.;
ATTENDING SURGEON, MOUNTAINSIDE HOSPITAL.

VALUABLE addition to our knowledge of hysteria may be obtained by following a few typical cases over a long period of years. Not only in its etiology but clinical history hysteria presents a mixture of both physical and mental symptoms. Earlier writers sought for and not infrequently found causes and symptoms that were distinctly organic. More recently chemical and cytological changes in the tissues have been looked for. The trend of the work of the French school, especially of such writers as Janet, Sollier and others, has been in the direction almost exclusively of a purely psychological interpretation of hysteria. The studies of suggestion and fixed ideas are the two lines of research that explain the problems of hysteria, and these we owe chiefly to the French.

Notwithstanding the enormous variety of the symptoms of hysteria, one common trait appears in all cases of this disease, perhaps the only one, and that is the possibility of its being reproduced by suggestion with rigorous exactness in proper subjects and of being dispelled by suggestion. "Man," as Boris Sidis states, is a "suggestible animal" and no matter how normal he is, if his attention is fixed, and distracted by some monotonous impressions, and if his voluntary movements and field of consciousness are limited, and his ordinary flow of thoughts inhibited for the time being he yields to suggestion. In the normal state a suggestion is more effective, the more indirect it is, and in proportion as it becomes direct it loses its efficacy. Or as Sidis states it, "normal suggestibility varies directly as indirect suggestion and inversely as direct suggestion." The Nancy school defines hypnosis as heightened suggestibility. Abnormal suggestibility varies directly as direct suggestion and inversely as indirect suggestion.

In normal men, the superior and inferior centers of the mind work in harmony, meaning by the upper, the will or choice centres or in other words the controlling and inhibitory centers. Physiologically, hypnosis is an inhibition of the inhibitory centers. It is a disaggregation of the superior from the inferior centers, necessarily followed, as in the removal of inhibition in general, by an increase of the ideomotor and ideosensory reflex excitability. Psychologically hypnosis is the split-off, disaggregated, organic reflex consciousness pure and simple.

Charpentier uses the word suggestion implying something harmful, and the word persuasion for suggestion that is in harmony with reality or good sense. For example, suggestion that a patient's arm will be or is paralyzed, persuasion that it will be cured. He defines hysteria as a psychical state rendering the subject who suffers from it capable of auto-suggestion, and the hypnotic state rendering the subject who undergoes it, susceptible of receiving direct suggestion from another.

Thus the purely psychological interpretation of hysteria explains its etiology in terms of suggestion and its primary symptomatology in the line of fixed ideas. Since the thoughts of a hysterical subject are rarely in a state of equilibrium, but unevenly balanced and subject to varying influences, one line of thought can readily develop in a manner so exaggerated and intense as to persist indefinitely to the great detriment of the mental and bodily health of the patient. This line of thought may become the condition of fixed idea or imperative concept which even to an uneducated observer is well beyond the borderline of sanity. In its extreme, hysterical psychoses resembling paranoia or other definite types of insanity may develop. Apart from these definite psychoses many less advanced cases of motor, sensory or visceral symptoms can easily be explained on the same psychological hypothesis. Bernheim calls attention to the fact that the serious symptoms or "grand crises of hysteria, are merely an exaggeration of the ordinary psychical and physiological phenomena seen under varying circumstances in normal human beings. He defines a hysteric as a subject who has a hysteria breeding or hysterogenous constitution, "appareil hysterogene" well developed and easy to be worked upon.

The clinical syndrome caused by exciting or depressing the nervous and psychical centers, developed by a shock or mental strain of any sort, instead of being temporary as in normal subjects and quickly disappearing, appears more quickly and readily degenerates into a prolonged attack with such general symptoms as convulsion, delirium, syncope, changes in sensation or local symptoms varied according to the individual condition of one or another organ. Hysteria, he states does not exist by itself. The hysterogenous state exists and various so-called hysterical symptoms may arise. It is characterized by a series of reactions, both physical and mental, and in a hysterogenous constitution, under certain causative influences, such as sudden moral or mental strain, or a more gradual impression, by the condition of nervous anxiety. All kinds of depressing impressions, whether they be such as are created by an incident of life, or suggested by an obsession of a fixed idea, are effective when focused on a hysteria-breeding constitution. Such general and local depression of a nervous nature, whether sudden or gradual, awakens latent hysteria in different ways. Vague sensations of discomfort or distress located in certain organs, or even an appreciation of their existence, and physiological activities, which normal people have no special knowledge of, a feeling of oppression, neuralgia, cramps or any other disagreeable sensation, form a substratum upon which basis, in a hysterogenous subject, hysterical symptoms may be built up.

Nervous anxiety may not always be present. Special impressionability of the potential hysteric ought not to be confounded with neurasthenia. The mind may be of a type prone to exaggeration and romance, but may seem morally and mentally normal. All the ideas are suggestible or autosuggestible.

In the symptoms resulting, what Richer calls a diathesis of hysterical contracture is apt to be present. While the patient presents no objective signs and preserves freedom of movement, the manifestations of his trouble may be brought on by the manipulation of his physician or some chance occurrence. This condition of the neuromuscular system partakes of paralysis in that it usually coincides with a weakness of motility, and of contracture in that the slightest excitement will bring it on, or cause it to disappear. It has been called latent contracture.

A second common condition in hysteria is seen in the vasomotor phenomena such as the flushes, morbid blushing, sensation of heat or cold on the surface of the body. In a case of typical traumatic hysteria seen by the writer a short time ago, showing well marked hemi-anesthesia and contracted visual field, over an area where a contusion had been sustained two years before, but where no scar or permanent injury was visible, an area of redness of the size of a half dollar would appear whenever she was subject to a strong emotion, and was especially noticeable when she sat in the witness stand. Here autosuggestion in producing definite paralysis of the vasoconstrictor nerves over a limited area, was absolutely demonstrated. In these cases salivation, local hyperidrosis, pallor, or hot or cold extremities are common. If the same vasomotor phenomena take place in the general sympathetic system, especially in the splanchnic or cardiac plexus, serious trouble from some of the internal organs may occur. Flatulence, palpitation or irregularity of heart are common examples. Fränkel reports several cases of death from such cases of hysteria with special interference with these

important parts of the sympathetic system, with no organic lesion of any sort found at the autopsy.

Edema of the lower extremities, from this cause, and if the spasm is prolonged, even local gangrene, as in Raynaud's disease, may occur. Many dermatoses of hysterical subjects, most frequently of the urticarial type show this reaction. Herpes especially herpes preputialis, occurring as it does in thoroughly neurotic subjects, and various familiar or rare types of skin diseases mechanically produced by vasomotor fluctuations can be classed with these conditions.

Given a neurotic subject, neurotic from bad heredity, or mal development passing through any of the critical periods of life, such as puberty, adolescence, pregnancy, the menopause, or old age, with the resisting power none too strong, and hysteria is almost inevitable if the subject has a hysteria breeding constitution.

Take a common example of the first or second period. A boy or girl falls into a state characterized by self-centered mentality, irritability, inability to work; anorexia, gastralgia, vomiting, or the symptoms described in detail in the patent medicine advertisement occur. Typical symptoms of hysteria, contractures, anesthesia, crisis or paralysis of one sort or another may follow. The condition is a neurosis of development. It is based on autosuggestion or unconscious imitation as a rule. It may be associated with toxemia of some sort. Sometimes the patient is able to suppress every symptom of a nervous nature except the anorexia, which may persist as an obsession which cannot be resisted. The moral inertia of such cases may persist until the cyclic evolution of the youth is completed.

Whenever, in such a case as this or in any other nervous or mental disease, anorexia becomes one of the definite symptoms, grave changes of the physical condition will result, such as emaciation, weakness or any objective and subjective symptoms ordinarily caused by starvation, of which anemia is the most frequent and serious condition.

Neuroses and psychoses of old people whether during the menopause, or the senile period are frequent. At this time hysteria is associated with such changes in the tissues as arteriosclerosis, aortic insufficiency, angina pectoris, asthma, and acid dyspepsia. Frequently the patient is not naturally hysterical or hysterogenous. Progressive changes of the patient in the last years of life, render the hysteria breeding constitution more impressionable. Hysteria is not created by the arteriosclerosis, but a hysterical diathesis is revealed by it and the capacity for resistance is decreased by it.

In women who have hysterical tendencies, the menstrual period with its physiological depression, is a time specially liable to develop definite hysteria, just as those prone to epilepsy, or even uricacidemia present their most marked symptoms at this time. Physiological congestion of the ovaries and minor displacements of one or another of the pelvic organs, have their effect in severe pain and other nervous symptoms which may be definitely hysterical. The whole train of what the patients term "female complaints" are a vicious circle in which hysteria is an omnipresent factor. It is difficult or impossible to state in a given case which is the primary and which the secondary factor.

A normal menstruation is not sufficient to reduce the number of red corpuscles in the blood, for, like all other slight hemorrhages, it sometimes increases the number of red cells and the hemoglobin. If other causes of anemia are added, a slightly disordered menstruation rapidly reduces the number of red cells, and hemoglobin, and definite anemia results.

General observation convinces every one that the two types of women from whom we expect hysterical symptoms, are the anemic and the poorly nourished women, and the fat women with hydremia; the latter look as if their color was good, but the mucous membranes or blood count show anemia. Ewing states that functional nervous diseases, such as hysteria, neurasthenia or hypochondriasis do not give rise to anemia, though associated conditions may lead to impoverishment of the blood.

In cases of hysteria associated with gynecological disorders, the gynecological lesions are presumably primary. Fibrocystic ovaries are common in later life without causing pain or nervous symptoms, and yet the same pathological condition may be associated with or cause intense neuralgic pain. And, as nearly all cases of hysteria show, the commonest of the so-called stigmata of hysteria is the "ovarie" or sensitive ovary, a similar painful area being frequently seen in male hysterics.

Practically all diseases can become hysterogenous especially those of the nervous system. Chorea and epilepsy frequently breed hysteria, and the symptoms of chorea and epilepsy can usually be proved to precede the hysteria. If they coexist, each disease preserves its distinct symptoms.

Tabes, hemiplegia following cerebral lesion, definite muscular dystrophies, all may be hysterogenous and have distinctly hysterical symptoms engrafted on them. Alcoholism and other toxic conditions, in hysterogenous subjects, can present a mixture of symptoms, which are not easily separated. It is usually as inaccurate to speak of alcoholic hysteria as hystero-epilepsy.

Admitting that various diseases may be hysterogenous, is the converse true? In typical cases of hysteria, in the course of time definite organic symptoms must appear. All hysterical cases must eventually die of something. What is the relation of hysteria with cardiac, urinary or intestinal symptoms which are obviously hysterical, to such genuine and ultimately fatal lesions as organic disease of the heart, the kidneys, or other organs? Naturally it is in the severer type of hysterical attacks that definite impression on the organs should be expected.

The symptoms of hysteria which appear in the earlier part of the history of a case are as a rule of moderate intensity, do not alter consciousness extensively, and even if they last a long time, eventually disappear. The hysterical seizures or attacks are just the reverse. They are acute, they make decided alterations of consciousness, they are momentary or last but a few hours. These attacks are fairly well known on account of their startling character and the necessity of distinguishing them from other convulsions of a far more serious nature. Not only the physical symptoms become more definite, but there will develop some modification of the respiration, circulation, and all organs under the control of the sympathetic nervous system. Janet makes seven types of hysterical attacks: (1) emotional seizures; (2) attacks of tics or clownism; (3) attacks of fixed ideas or ecstasies; (4) complete attacks, hysteria major (Charcot); (5) automatism in the attack and in the fixed ideas; (6) somnambulism; (7) delirium.

The first physical change resulting from convulsive disease may be looked for in metabolism and especially in the urinary secretion. Hysteria is always associated with such modification. Polyuria of a low specific gravity is one of the most constant physical symptoms of hysteria. Long-continued reduction of the total amount of urea is described by Janet and others, and the reduction may last for months (two grams daily in a total of 100 grams of urine). Other cases continued to pass less urea than has been supposed possible for any length of time without fatal results. Charcot reported anuria in a hysterical case lasting eleven days without any symptoms of uremia. Lowenfeld explains this as due in some cases to diminution of metabolism and the slight production of the material that causes uremia. In other cases, or perhaps usually, the most reasonable explanation is the cramp of the vessels of the kidney, like the vasomotor disturbances previously alluded to, which are so common in hysteria, and in this case easily modify the secretory function of the kidney to a greater or less extent. The typical urine of hysteria is large in amount, low in specific gravity; the solid ingredients, such as urates, phosphates, chlorides are diminished to about one third of the normal; and the ratio of earthy phosphates to alkaline phosphates instead of being 1:3 are 1:1. In a recent experimental study by Castaigne and Rathery in *La Semaine Médicale* it is stated that lesions were found in the kidney wherever polyuria was known to have existed during life, and lesions were found in rabbits every time polyuria was induced for a certain length of time.

Albuminuria may be found after violent convulsive attacks. This is common after violent epileptic attacks. Galanti, in repeated examinations of the urine of 16 epileptics, found, after the epileptic seizures, albumin in quantities varying from 0.05 to 2 per cent. The duration of the albuminuria was from four to six hours. If albumin was present in the urine of these patients, it was much increased after the attacks. He explained the albuminuria by (1) renal stasis secondary to the initial stage of the fit and the dyspnea; (2) by cerebral excitation at the cortex and bulb; (3) by the toxic influence upon the renal epithelium; (4) by change in metabolism and intestinal toxemia; (5) by the intense muscular work. Nearly all these factors are present in a severe hysterical attack. That albuminuria may be associated with hysteria, whether as an etiological factor or, as is more probably the case, as a result is illustrated by the following case under observation by the writers of this paper and many physicians in Brooklyn:

The patient was a trained nurse, aged twenty-five years, born in Scotland. Her father is neurotic, and somewhat of an invalid from chronic bronchitis. Her mother was at one time insane and died of phthisis. Her previous health was good. She was addicted to the excessive use of coffee. She suffered from great mental depression after her mother's death, shutting herself up in her room for several days, and also from the effects of a severe contusion of the knee, for which she wore a knee-cap for a long time, because she believed it had been fractured. When she entered the training school, her fellow nurses say that she appeared somewhat slow mentally, studious, absentminded, and forgetful. They had not considered her as especially nervous in temperament. Although she studied hard, she seldom learned her lessons perfectly and this worried her. She was well liked on account of her sweet, obliging disposition and manners, and her desire to do her work well. She had an unfortunate love affair while in the training school, which affected her severely. At this time some slight breach of the rules of the hospital, which caused her to be reprimanded, had the effect of making her feel that she was an ill-used person, and made her crave sympathy and consolation from others.

December, 1899, she came to the Brooklyn Hospital from outside nursing, complaining of symptoms of influenza. After working a few days more she returned complaining of pain in her eyes. She said she had been nearly run over by a trolley car, because she could not see it. But immediately after this had happened, she was seen to look up an oculist's address in the telephone book. She was under his treatment for some weeks for internal strabismus of the right eye. About this time she had an attack of nausea and faintness in the doctor's office, associated with feeble heart action and alarming general symptoms. During the following days, though working, vertigo and unsteadiness persisted. Four days later the patient was suddenly seized with convulsions which were diagnosed by two physicians as uremic, though their examination of urine had been insufficient. She was sent to the Brooklyn Hospital in an ambulance, chloroform being administered en route. She reached the hospital unconscious. Her respiration was deep and stertorous; her pulse 88, soft and moderately

forcible. Her temperature was 100° F. She was put in a hot pack for a while, reflex movements occurring while in it, but little diaphoresis. Examination of urine showed no albumin; a specific gravity of 1.036, abundant urates and phosphates. As it reduced Fehling's solution a conjectural diagnosis of diabetes was made, but before the result of this examination was reported, the patient reacted to supra-orbital pressure and cried out when allowed to inhale aromatic spirits of ammonia. No glycosuria was present, the examination having been made hastily by gaslight.

She remained in the hospital for six weeks; her mind being clouded most of the time. At the time of her discharge her bodily health was good but the ocular symptoms returned. There was internal strabismus of the left eye. The pupils reacted to light and distance. The patient complained chiefly of diplopia. Some observers diagnosed her case as tuberculous meningitis. The mental symptoms improved, but loss of memory and inability to recognize her friends or name them correctly persisted. She improved but complained constantly "that people did not seem the same." A nurse in the hospital gained a remarkable control over her, so that the patient was said "to have been hypnotized by her." No new physical symptoms were recorded and examination of her urine was always negative.

After her discharge from the hospital, the patient remained in good health excepting her memory. She went abroad and joined her family, but suffered considerable fatigue and nervous strain, however, from having to nurse her father through pneumonia. A year later she came to a New Jersey town to nurse a confinement case. Unexpected delay and responsibility in connection with this case worried her very much.

October 7, 1900, she was found on the kitchen floor in clonic convulsions. The movement of the limbs were rhythmical, making rather small uniform excursions. There was some opisthotonos, the head rotating slightly. The eyes were wide open, turned to the left, the pupils dilated and fixed, but there was no strabismus. The facies was dark and cyanotic. The fists were clenched and the thumbs turned into the palms. The pulse was imperceptible. The movements became weaker until the patient lay quiet but seemingly comatose. A prick of a needle, administering a hypodermic of apomorphine brought on another convusion lasting fifteen minutes. Chloroform had to be administered. She was taken to the Mountainside Hospital in an ambulance, showing on examination that her tongue was bitten, she had suffered contusions and ecchymoses from the convulsions and had micturated involuntarily. She had in all three or four distinct convulsions, the first one having been ushered in by a pain in the bowels and headache and general malaise.

The urine was examined by the pathologist of the hospital, and was found to contain a considerable quantity of albumin (1 per cent. by weight), and the specific gravity was 1.015. Thirty-two ounces had been passed in twenty-four hours exclusive of what had been lost in the stools. She had a few hyaline and granular casts.

The record of the first night was marked only by some involuntary micturition, occasional vomiting, and a mental condition dazed or mildly delirious, at times uncontrollable. She was sent to the Brooklyn Hospital soon after, going quietly with her friends and recognizing the people in the hospital but not realizing where she was. The records of the hospital give the following account of her condition on admission.

General appearance and attitude, well nourished, nervous and restless. Cheerful manner, mannerisms or peculiarities of dress or posture. Reaction to surroundings interested, to questions fairly coherent, attention fair, content of thought not absolutely fixed but centered upon her father's voice who kept calling to her from the next room. Consciousness, orientation for time absolutely lost; she said she had been in the hospital for three years. Orientation for persons and places also defective. Confused memory for both past and present events. Interest and judgment not apparently affected. Fancies she sees persons not present; hears voices that are not existent. The hallucinations of sight and hearing are fairly constant. No depressive, expansive or fixed delusions. Emotional condition, not especially disturbed. Physical condition: No stigmata recognized. Reflexes normal.

For a fortnight her urine showed in five examinations a faint trace of albumin with granular and hyaline casts. The examination showed no changes in sensation or reflexes excepting the loss of the palate reflex. Two weeks later the patient left the hospital "improved," with a diagnosis of "hystero-epilepsy." The diagnosis in the same institution some years before having been hysteria.

One year later the patient was seen to be in apparently good health and had grown somewhat stouter. She had been able to work and had not been sick excepting for a period of three days, when she had been living in a nurses' boarding house. Her mind was a blank for these three days and she does not remember what happened. A physician consulted by her diagnosed some gynecological condition and treated her for it, advising an operation. She still has headaches and these are at times preceded by pain over the ovarian region, and characterized by feeling of great pressure across the eyes. Repeated examination of the urine shows no albumin or casts. She is at times constipated, has some leucorrhea. There is no gynecological lesion at present existing. She still dreads another "turn," which has not appeared for a year. The family surroundings and improved prospects have doubtless helped to bring this improvement about.

This case, related in detail, presents marked difficulties of diagnosis as between organic disease, such as uremia and functional nervous disease, and again, still greater difficulty if one would discriminate between hysteria and epilepsy.

The symptoms of her convulsive attack carefully summed up in parallel columns in the style of text-book diagnostic tables, which compare epilepsy and hysteria give out of 18 points, 5 unmistakably referable to hysteria and 11 to epilepsy. The fact remains that the clinical history followed over a period of years clearly proves that it is the record of one suffering from hysteria in ever-varying phases. There comes a time when careful and repeated examination of the urine shows for a brief period the casts and albumin, usually associated with definite organic disease of the kidney.

The supposition that there was nephritis as an underlying cause of the whole train of symptoms, or any important part of the symptoms, cannot be maintained, however.

Case II.—M. S., an American Hebrew, of the dark and handsome features type; giving a definite neurotic family history. He had recently passed through serious business trouble and had lost most of his money. When first seen by the writer he announced that he was about to have "one of his colics" and requested that if he should, ether or chloroform be administered to him, as morphine always crazed him. He said he had had a stone crushed in his bladder. He had had numerous "nephritic colics" and had traveled all over Europe to various health resorts. He had passed no stone recently. Then ensued a series of the most violent attacks imaginable attended with intense pain in the region of the kidney, running down to the penis. He was extremely nervous and after injections of morphine, he became so wildly delirious and unmanageable that he tried or pretended to try to throw his physician out of the window. Local examination showed a sensitive urethra, an enlarged and tender prostate and tenderness in the region of the left kidney. The urine contained the faintest suggestion of a bloody shred or clot but no hematuria or stone. During this and succeeding attacks his manner was what is commonly called "hysterical," though he showed no hysterical stigmata. After frequently recurring attacks of the nature described, all physicians associated with the case being fairly worn out by the way he yielded to them, and his obvious danger of incurring the opium habit, I talked with extreme frankness and roughness to him about it, telling him, what I only half believed myself, that he was imagining the whole thing. I never saw him for six months, when, meeting me on the street, he told me that the talk had been the "turning point of his whole life," and that he had never had an attack since.

The early history of this case was positive as to his having had a calculus. Admitting the organic basis of his earlier trouble, he was a neuropath, had a "hysterogenous constitution" and was undoubtedly perpetuating his genuine nephritic colic indefinitely as a hysterical echo until "called down" and shamed into common sense. All surgeons who have operated for stone in the kidney and after cutting down, have found no stone or any other lesion of the kidney will find in the features of this case many points that resemble their own cases. It seems reasonable enough to conclude that insignificant trouble in the kidney, or anywhere else may, in a neurotic subject, by concentrating his thoughts to that region produce puzzling hysterical-organic symptoms.

VARIETIES OF PULMONARY TUBERCULOSIS.

BY JAY PERKINS, M.D.,

OF PROVIDENCE, R. I.;

PHYSICIAN TO DEPARTMENT OF PULMONARY TUBERCULOSIS (OUT-PATIENT), RHODE ISLAND HOSPITAL.

Most text-books give no divisions of pulmonary tuberculosis, which are of practical value either in prognosis or treatment, merely stating that some cases recover and certain cases die. The results in our sanatoria show that some apparently early cases fail to recover, or sometimes even to improve, under the excellent treatment which is given them. Some patients leave home and rough it and get well; others go away and, under the same conditions, fail and perhaps die. Many, as shown by autopsies, have the disease and recover without knowing that they have had it; others are near death before the disease is recognized.

During the past few years no disease has received greater attention or had more able minds devoted to it than has this same old scourge, consumption, and though much remains to be learned a more accurate knowledge of the disease is being obtained. A careful study of the pathological aspects of tuberculosis has shown the relation between the early and the healed process, also the condition of the lungs in arrested cases. The chronic, slowly progressive cases, the rapidly progressive localized cases and, finally, the general infections, have been thoroughly studied pathologically and are familiar. Now the problem is to learn to recognize these forms from a clinical point of view early in the process, for by doing this we come as near as is possible to being able to give a reasonable prognosis. Ability to prognosticate the probable course of the disease is of vital importance and will save many of the mistakes now made in sending patients far from home and among strangers to endure unnecessary hardships and disappointments, and will also aid much in individualizing treatment.

Putting aside for the moment the fact that patients with pulmonary tuberculosis can recover at home, the day is far past when it was justifiable to send patients away to face unknown conditions simply because they were found to have tuberculosis. No climate is a cure-all for any case of tuberculosis, and no climate is of advantage to all forms of it. No one treatment will benefit all cases of pulmonary tuberculosis, and the treatment which will cure some is a positive injury to others. The successful handling of a case of pulmonary tuberculosis, whether such handling consists of advice as to where to go for treatment or of the actual treatment itself, depends upon a recognition of the form of the disease and its probable course and upon the

characteristics and condition of the individual; not upon the single fact that he has tuberculosis. The known individual and not the disease should be treated. The writer has been trying for some time to get a classification of cases of pulmonary tuberculosis and from a study of his own patients and from the recorded experiences and researches of others has accepted the following as a general classification. Of course these forms are not absolute but merge into each other, and, indeed, different forms may be found in different localities in the same individual at the same time, or the disease may be masked by accompanying conditions in the lung, as bronchitis or emphysema. Yet a classification will do much to help us avoid mistakes and in other ways benefit our patients.

First: Localized fibrous form.—Nature's way of cure is by fibrous tissue, and these fibrous cases are the favorable ones. The disease begins in mucous membrane or pleura and fibrous tissue forms and encloses the diseased tissue, the fibrous extending much farther than the tuberculosis tissue. There is little or no necrosis of the lung tissue and little mixed infection. The process is slow and may be sharply localized or may become widespread. These are the most favorable cases and the ones that can endure the most vigorous treatment.

All cases which recover or improve give a certain amount of fibrous thickening, and the most favorable of all are those having a sharply localized tuberculous focus, usually at one apex. Fibrous thickening of that apex occurs and segregates the disease from the healthy tissue. Cavities may occur, hemorrhages may take place and caseous matter may be expelled; yet the disease remain localized. The apex may be considerably affected and recovery still take place because, not only does the shutting off of the disease area by fibrous tissue prevent the spread of the infection but it also limits the absorption of poisonous products into the circulation, thus preventing much of the possible constitutional involvement. Even though the original infection is quite severe, so that, before the fibrous tissue has time to form, a considerable tuberculous mass is present which later breaks down and forms a cavity of appreciable size, we have the disease arrested, and in time perhaps cured, if the lung has the ability to take on a marked fibrous change about the diseased area.

Usually, by the time these cases come under observation so as to be recognized the fibrous tissue has begun to form, and we get slight dulness with some râles especially after cough, and harsh breathing with prolonged expiration at one apex, with slight constitutional involvement. That is, the actual consolidation is slight; harsh breathing beyond the râles shows the fibrous involvement and the lack of systemic poisoning shows the lack of absorption. Cases in this stage are the most encouraging for climatic or other treatment and the majority of the cases the writer has seen recover have been of this form.

Second: Fibro-caseous form.—The disease may take on this fibrous form and arrest occur after a considerable portion of the lung substance has become affected. Then we have the formation of a large cavity, contraction of the lung, and, if it is on the left side, the uncovering of the heart. Even with marked local disease the patient may live a long time in fair comfort, but with lessening of the breathing capacity, shortwindedness and debility. Or, without the formation of a large cavity we may get an extensive thickening of the lung substance by the formation of fibrous tissue and marked contraction of the lung. This may be limited to one side or there may be bilateral involvement. This condition as the localized fibrous form, may become stationary and the patient live years with a lessened vitality, but, under favorable conditions in fair comfort, a little wheezy, perhaps, but, by the avoidance of dust, smoke and all excesses, may enjoy a quiet, hygienic and comfortable life.

Third: Fibroid phthisis.—Generalized fibrous form.—How far these cases are of tuberculous origin seems to be a subject for further study. The writer believes that many, at least, begin as a result of some other irritant than the tubercle bacillus and that when this is present it is as a secondary feature of the disease.

In these cases there are general fibroid changes throughout the lung. They run a chronic course and are found chiefly among persons exposed to the inhalation of irritating dust, such as miners and workers on emery wheels.

Fourth: Phthisis florida.—This variety is without the formation of fibrous tissue. It begins with a profound and active infection, is not shut off from the healthy lung tissue, the blood vessels are not closed by the growth and contraction of fibrous tissue and the absorption is marked. The patient becomes cachectic and has a high fever from the toxins of a mixed infection. The disease shows only very temporary abatement or none at all and the patient dies of toxemia without the disease spreading to other organs.

*Fifth: Chronic parenchymatous tuberculosis.**—Closely associated with phthisis florida is what Dr. W. N. Biggs, in the Medical News of April 25, 1903, describes as "chronic parenchymatous pulmonary tuberculosis," corresponding with Powell's "chronic tuberculous phthisis." This is the form which is most frequently sent from home to die. The onset is very insidious and it is the form which most frequently escapes detection in the early stages, being diagnosed by the patient or physician as "debility," "anemia" or "bronchitis." The disease begins and spreads in the intra-alveolar tissue without much involvement of the bronchial mucous membrane and is accompanied by very little secretion, giving little or no cough and expectoration unless non-tuberculous bronchitis is also present. There is an induration of the alveolar walls and a more

* I do not like the name "chronic parenchymatous tuberculosis," but as this name has already been used and I have no satisfactory substitute, I use it.

gradual necrosis than in any of the other forms except the fibrous. Although there is a thickening of the walls of the alveoli, there is not a distinct fibrous formation and no shutting off of the diseased area by a fibrous wall. The early stages are marked by a slight or moderate rise of temperature, anorexia, anemia and loss of strength, while there may be but little loss of flesh until the disease is advanced. Hemorrhage is rare. On physical examination, even in cases past the initial or incipient stage, we find on percussion but slight impairment of the resonance or of vocal resonance and fremitus. As the alveoli are not filled to any extent there are no signs of consolidation and there is no cavity formation. The disease is steadily progressive and later we get some dulness, but not flatness. Then the breathing is harsh, but not the bronchial breathing of consolidation, with subcrepitant or sonorous râles followed by coarse, moist râles. If the affected area is contiguous to the heart, the heart sounds will be transmitted with abnormal distinctness. The heart is usually rapid out of proportion to the fever. A prominent characteristic of this form of pulmonary tuberculosis is the marked general symptoms as compared with the physical signs as given by auscultation and percussion. This form is less rapid, though but little, if at all, less fatal than phthisis florida, and patients thus suffering should not be sent away from home with any idea of cure, and should never be sent away alone. They cannot stand as vigorous a treatment as is beneficial to the fibrous cases.

Sixth: Acute miliary form.—This may exist by itself, as where a bronchial gland breaks into the pulmonary artery, or as a part of a general miliary tuberculosis. Here we get a condition throughout the lung similar to the parenchymatous tuberculosis which is local in one part of the lung in the beginning. The miliary form does not advance to the stage of dulness and mucous râles before the system is overwhelmed by the absorption of toxins. The physical signs are those of the early stage of the chronic parenchymatous form, except that they are general instead of local.

POISONING BY THE WHITE OF AN EGG.

BY J. R. CLEMENS, M.D.,
OF ST. LOUIS, MO.

That the condition or rather idiosyncrasy of poisoning by white of egg must be a very rare one is evidenced by the fact that no mention is made of it in the literature, even Vaughan and Novy's "Cellular Toxins" being appealed to in vain. The case I am about to record is interesting from the difficulty of the differentiation of the cause and from the extreme susceptibility of the patient to the effects of even minute traces of egg albumin in the gastro-intestinal tract, the gravity of the seizure being apparently out of all proportion to the exciting cause.

The patient, a child of fourteen months, during a moderately severe attack of whooping cough that was already declining, was suddenly seized one afternoon with an attack of acute urticaria and alarming collapse, the face and ears being greatly swollen and the radial pulse withdrawn from the wrist. The child was apparently moribund, but hypodermics of strychnine tided over the crisis. Later the child vomited the contents of the stomach: water and mucus. The pupils were widely dilated during the attack and the face pale. The child rallied slowly and was the source of anxiety for the following two days.

Antipyrin and the vapo-cresolene lamp were laid under suspicion and both discontinued. Some two weeks later an exactly similar attack was experienced and this time, as both antipyrin and carbolic acid intoxication could be excluded with certainty, other causes for the condition were sought for in vain. A month later the child, after partaking of some custard, suffered within half an hour from an acute attack of urticaria of the face and ears with vomiting and purging. The cause of the attack was now evident. Three days ago, after eating a small piece of gingerbread cake, in the making of which two eggs had been used, the child was noticed to be limping and on examining the feet both were found to be extremely swollen and purpuric, petechiæ and ecchymoses extending up as high as the middle of the legs. There were no nervous symptoms.

Treatment consisted in cleaning out the gastro-intestinal tract with oil, followed by full doses of calomel as an antidote and later by salol and magnesium sulphate. The recovery was uneventful, the edema of the feet rapidly disappearing, although the child was allowed to stand and walk.

Points of interest bearing on the case are the facts that the kidneys are sound and that each attack was preceded by weeks of intestinal indigestion as evidenced by pale stools, flatulence, flabby muscles and broken sleep, a great amount of indican being observed in the urine. A short time prior to each of the first two alarming attacks the child had been given the white of an egg with his milk, which was an innovation. Whether the child would prove immune to eggs when in full health is an experiment I have no desire to make.

All four attacks were without incubation periods and must therefore have been intoxications. Atropine was contraindicated by reason of the condition resembling that of atropine poisoning. The family history is negative in regard to any such idiosyncrasy. The possibility of a future attack expending itself on the larynx must ever remain a cause of anxiety.

Dr. Bull Resigns from Columbia.—Dr. William T Bull tendered his resignation on Monday last as professor of surgery at Columbia University, to take effect June 30, and it was accepted. Dr. George E. Brewer, professor of clinical surgery, was assigned to a seat in the faculty of medicine. Dr. T. Matlock Cheesman was elected a trustee to succeed Dr. Edward L. Trudeau.

MEDICAL PROGRESS.

MEDICINE.

Antimalarial Operations.—Tropical medicine is apt to become as popular in this country as it is in England. J. W. W. Stephens (Lancet, March 5, 1904) recites the results of his experiments at Mian Mir, Punjab. He states that the commission of which he was a member became convinced that the fundamental measure in the antilarval crusade was drainage. The intensity of malaria, or as it has been called, the "endemic index" of a place, can be easily and accurately determined. It is necessary to examine a number of blood films, 25 is sufficient, taken from children under ten years of age dwelling in the district. This gives a percentage of those with parasites in their blood. Before the commencement of operations, all these conditions were accurately determined by a malarial survey. The importance of the introduction into sterilized regions, of *Anopheles* on carts, wagons and conveyances of various kinds, cannot be overestimated. It is discouraging to note that the report states that after two years of persistent work, as measured by the test of degree of improvement in the troops during the fever season, the outcome was *nil*. The conclusions of the commission in part were: First, that in quinine administration to the children and in abolition of infecting sources, one has the only means as yet devised for positively improving and safeguarding the health of the troops. In order that fundamental change, however, be made in the absolute well-being of camps situated in malarial districts, radical changes will probably be necessary in the entire system of irrigation and of water supply. For the time being, however, it is obviously necessary to depend simply upon quinine and segregation.

Some Observations on Kidney Cases.—H. Quincke (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) praises the action of potassium chlorate in cystitis, but urgently warns against its use where a pathological condition of the kidneys is suspected. In one case of congenital cystic kidney and in another of bilateral hydronephrosis, the drug hastened the fatal issue, though only four grams a day had been ordered. Since at one of the autopsies, an enlarged median lobe of the prostate was found, which had not been diagnosed during life, a sound with a lateral depression along its lower aspect near the tip was constructed, which is especially serviceable in such cases, since one can readily feel the depression pass over the lobe as the sound passes into the bladder, especially when the finger is inserted into the rectum. Attention is also drawn to a peculiar finding in the urine of a case of unilateral hydronephrosis; the sediment was rich in cells 24 to 36 mikra in diameter, with their entire cell-body filled with very coarse granules, disappearing after the addition of acetic acid. These elements were probably epithelial cells derived from the straight tubes altered by pressure; since they were subsequently found in similar cases; they are of diagnostic value and indicate that a slow atrophy is in progress. Fibrinuria is also occasionally observed here and in interstitial nephritis; the urine is often faintly alkaline and if allowed to stand, will deposit delicate filaments mixed with triple phosphate crystals.

Aortic Aneurism of Traumatic Origin.—Though by far the greater majority of aortic aneurisms have their origin in a syphilitic process within the walls of the artery, there is little room for doubt that trauma was the sole etiological factor in the case of A. Heller (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4). A laborer was suddenly obliged to carry a very heavy weight, resulting in an acute dilatation of the beginning of the aorta with the tearing off of a portion of the wall. At the same time two aortic valves were torn, leading to an acute insufficiency with dilatation of the left ventricle. The resulting fall in pressure permitted the tear in the aorta to cover itself with intima, but the rest of the wall slowly developed into an aneurism. Microscopically the picture can be clearly differentiated from a specific process; in the one the elastic fibers of the media are everywhere pushed apart and torn, while in the other, a small-celled infiltration with giant-cells accompanied the nutrient vessels through the media and adventitia, while later portions of the media become necrotic.

Paroxysmal Hemoglobinuria Due to Cold.—In this peculiar form of hemoglobinuria, general exposure to cold or the mere immersion of a limb in cold water for a short period, will be followed by the discharge of a bloody urine. J. Donath (Zeitsch. f. klin. Med., Vol. 52, Nos. 1 and 2) removed some blood from the finger and placed it upon ice for a varying length of time, but could not detect any solution of hemoglobin, so that other factors besides cold must be at play. The blood was then actively shaken to determine if the corpuscles possess less resistance toward mechanical influences, but the difference from normal was so slight as to be unimportant. Simple ligation of an extremity sometimes gave rise to hemoglobinemia in the affected part, sometimes not. A number of other experiments did not lead to any very positive results, yet it seems likely that the entire process depends on a hemolytic action of the blood serum caused by the presence of serum hemolysins.

SURGERY.

The After-effects of Head Injuries.—There is no subject more rife with interest than this, because it touches upon the most vital part of man—the mind. T. C. English (Lancet, March 5, 1904), from an exhaustive study of the subject of traumatic epilepsy, late traumatic cerebral abscess and traumatic insanity concludes: (1) While some degree of mental impairment is comparatively common after injuries to the head, the changes are seldom sufficiently marked to be included under the heading of insanity. (2) Insanity may result from injury to any part of the head. (3) Traumatism leads to insanity in two ways, (*a*) direct insanity due to the actual injury to the brain or its membranes apart from hereditary or other predisposing causes; and (*b*) indirect insanity, that is to say, any form of insanity occurring as the result of lowered resistance of the brain due to injury in patients with a predisposition to insanity, hereditary or otherwise. (4) Every variety of mental change may be produced by traumatism, although some forms are commoner than others. (5) It is at present undetermined whether injury to the prefrontal region is more likely to be followed by mental disturbances than injury to other parts of the brain. (6) Only a small proportion of the cases of traumatic insanity are open to relief by operation, for a localizing indication in an accessible region must be present. (7) The results so far have been encouraging, and although the operation must necessarily be exploratory, it is fully justified in suitable cases, especially in face of the otherwise hopeless condition of these patients.

Oxygen Gas for Cystoscopy.—Carbolic, boracic and many other solutions have been used for this purpose, but all have more or less marked disadvantages. A. G. Faulds (Brit. Med. Jour., March, 1904) states that one of the advantages of using a solution instead of gas to distend the bladder is that the fluid dissem-

inates the heat and thus saves the mucous membrane from being injured. Unfortunately, however, it allows of the solution of blood and pus, which render the fields of vision obscure. Cold lamps, however, so called, are now fitted to cystoscopes, and these enable the operator to discard the fluid medium. It is well to distend a rubber bag, which contains the average amount expected of a urinary bladder with the oxygen and then slowly to force this through a tube into the bladder. The advantages of oxygen are obvious, particularly in the case of bleeding tumors or bleeding mucous membrane or purulent conditions. The oxygen undoubtedly has an ameliorating effect on any form of cystitis. It seems to give tone to the bladder wall and to purify the urine. If the cystitis should be marked, it may be necessary to use a local anesthetic. After removal of the cystoscope, the oxygen should be left in the bladder to exercise its disinfecting properties.

Lip Tie.—Cases of tongue-tie, while uncommon, are of sufficiently frequent occurrence to be well known. F. GRIFFITH (Ann. of Surg., March, 1904) states that a shortening of the frenum of the lips is not cited in literature. A case recently occurred in his practice which was so marked that the infant, a child of Italian parentage, presented this abnormality to such a remarkable degree that it necessitated operation. The midline of the entire upper lip had been bound to the gum by a fold of tissue continuous with the mucous lining of the mouth, one-eighth of an inch in thickness. The teeth were small but well formed. On opening the mouth, the middle of the upper lip rolled directly inward giving rise to a peculiar expression not apparent when in repose. The direct family history was negative. Treatment consisted in simple section of the frenum.

Penetrating Wounds of Abdomen.—Having positively determined that the wound has entered the abdominal cavity, there are two main questions to be considered, viz., Has any viscus been injured? Is hemorrhage taking place? Unfortunately there are no classic symptoms grouped about the penetration of stomach, intestines, spleen, liver or pancreas. Shock, it is true, subvenes sooner or later, but unfortunately in too many cases the first definite symptoms of perforation are those of the inflammatory reaction in the peritoneum which, when manifested, indicate, whatever the treatment, a lethal termination for the case. M. L. HARRIS (Ann. of Surg., March, 1904) states that the most important factors which have enabled surgery to produce a recovery percentage of over 90 per cent. instead of a mortality of 70 per cent., as was the rule under the old form of medical treatment, are, first, immediate operation, and second, drainage whenever the gastro-intestinal tract has been opened. After citing a large number of cases, upon which he had recently operated, the author emphasized the following points: (1) In penetrating wounds of the abdomen there are absolutely no known symptoms which indicate injury to any of the viscera except those noted above in connection with the urinary tract, stomach and occasionally the lower bowel. (2) Except those relating to general shock, all symptoms following such wounds indicate either internal hemorrhage or peritonitis. (3) To wait for symptoms of perforation of the intestines means to wait until peritonitis has developed, therefore (4) every bullet or stab wound which penetrates the abdominal cavity should be operated upon at the earliest possible moment, in order to anticipate the advent of peritonitis. (5) No time should be wasted in attempting to demonstrate the presence or absence of intestinal perforation by such means as the rectal insertion of gases or vapors, or the analysis of recollected intraperitoneally injected air or liquids. (6) It is essential to systematically examine the entire gastro-intestinal canal in all cases regardless of the point of entrance of the wounding body. (7) Whenever the alimentary canal has been perforated suitable drains should be placed either through the operative incisions or counter incisions, as may appear best suited to the individual case.

Surgery of Perforating Gastric Ulcer.—Thanks to the influence of Mr. Mayo Robson, the English physician is probably better prepared to diagnose this condition than his American colleague. This probably, rather than the belief held by some that the disease is more frequent in England than in the States, explains the divergence in the reported cases. William J. Mayo has done more than any other person in this country to impress upon one the frequency of gastric ulcer and the unimpeachable necessity of treating these cases by radical surgical procedure rather than by the temporization of medicine. ARCHIBALD MACLAREN (Ann. of Surg., March, 1904), in support of these statements cites the interesting facts that prior to the remarkable work of Lawson Tait, ectopic gestation was looked upon as a curiosity. Nowadays it is of very common occurrence; this simply because of the increased ability in diagnosis. Although the author believes ulcer to be as frequent in this country as abroad, he does not consider that perforation is at all as common. Out of Mayo's 313 operations on the stomach and the first portion of the duodenum, there were only five perforations. At the Massachusetts General Hospital, in 187 consecutive cases of gastric ulcer, there were but six perforations, all of which died. On the other hand, from 1897 to 1902, in 500 cases of gastric ulcers in the London Hospital, 48 died from peritonitis and perforation. Fenwick found that in 678 autopsies with open gastric ulcer, perforation had occurred in 23 per cent. Moynihan in the Lancet (January, 1903) reports 51 perforating duodenal ulcers, in most of which a mistaken diagnosis of appendicitis had been made. All authorities agree that whereas gastric ulcers are more common on the posterior wall, acute perforations are usually on the anterior surface. The posterior ulcers are of a chronic type and are apt to lead to subphrenic abscess. As is well known, the premonitory symptoms of gastric ulcer are usually well marked. In a certain proportion of cases, however, these may be absolutely lacking and it is interesting to note that this is the condition which exists typically in the ulcers of the anterior wall, which, as before noted, are of the acute perforating variety. The immediate symptoms of perforation are the agonizing, overwhelming pain which, as stated by Fenwick, often causes the patient to fall unconscious to the ground. Hart, of Philadelphia, is, in the opinion of the author, correct when he states that rigidity of the abdominal muscles is the keynote to the early recognition of peritoneal perforation from whatever source. The pain may subside, the temperature likewise, but the rigidity will continue to the end. Vomiting is seldom present with perforation. Subacute or chronic perforations do not present such typical symptoms. They are milder and slower in development, often giving the classic symptoms of a local peritonitis or of an intraperitoneal abscess located near the stomach. The obvious treatment of all these cases is first to give enough morphine to still the terrible pain and then, without delay, have the case removed to a hospital. Operation at the earliest possible moment is indicated, the mode of toilet of the peritoneum being determined by the amount of escaped contents. In every case the Fowler position should be used.

Operative Treatment of Habitual Subluxation of the Patella.—As is well known, this annoying lesion is most difficult to treat. The sesamoid duplicature of the patella tendon almost invariably dislocates outward,

the cause of this being probably a double one. First, because of the nature of the articular surfaces, and second, because of the moderate amount of knock knee which is always present in a varying degree. When the quadriceps contracts, the tendency is to throw the patella out, because the line of force is a triangular one. Ali Krogius (Zntrlbl. f. Chir., March 5, 1904) cites some of the methods which have been employed for the correction of the deformity. Bajardi has resected a portion out of the median line of the capsule. Le Dentu and Bardenhauer have adopted various methods of reducing the size of the capsule. Roux has transplanted the ligamentum patella. Lucas-Championnière and Pollard have endeavored to accomplish the same means by a deepening of the patella fossa. Heineke has transplanted the tuberosity of the tibia. Trendelenburg has endeavored to raise the outer condyle of the femur. Of all these methods, the capsule splitting of Le Dentu, either in its original form or in Kocher's modification, seems to have the widest range of use. In the case under consideration, there was no indication for bone operation, and because of the discouraging ease and persistency with which the patella was dislocated to the outer side, it did not seem as though the ordinary plastic operation of the soft parts would suffice. The method chosen was as follows: On the outer margin of the knee a curvilinear skin incision is made, similar to that employed by Kocher for resection of the knee. The flap is then carefully lifted from the center of the knee over the patella and also laterally, so that the whole front portion of the knee is exposed. Next a cut, one millimeter distant from the outer margin of the patella, is made. It begins a finger's breadth above the patella and ends opposite the tuberosity. This cut transfixes the iliotibial band over the lateral tendon of the vastus internus. The incision is then carried down through the tissue of the vastus internus, following so nearly as may be in the directions of the fibers of the muscle. About two fingers' breadth to the inner side of this a second incision is made parallel to the first in the lower portion, but diverging above. The flap is then raised and the defect repaired by catgut suture. This bridge-shaped strip is then carried across the patella and held in position on its outer margin with catgut sutures. The skin wound is then closed and the leg immobilized for three or four weeks. In particularly aggravated cases, this operation could be combined with the transplantation of the insertion of the ligamentum patella to the inner side. The results of this technic are good.

Renal Decapsulation for Unilateral Hematuria.—The old teaching that whenever hematuria was present, the cause was probably stone, tuberculosis or malignant growth in the kidney or papilloma of the bladder, has been somewhat upset by the impetus which has been given to investigation of this subject through the efforts to cure through decapsulation. Leonard Freeman (Ann. of Surg., March, 1904) states that tuberculosis is probably the most frequent cause of obscure renal bleeding. Next in frequency comes chronic nephritis, usually of the interstitial type and often attacking the glomeruli. It may be bilateral or unilateral. It may involve the entire kidney or appear in small portions of the organ only, which has often, no doubt, led to its non-recognition. Few physicians, the author states, seem to be aware that copious and prolonged hemorrhages may arise even when the disease is limited in extent. The precise manner in which decapsulation acts in these cases is not thoroughly understood. Inasmuch as other operations, particularly nephrotomy, acupuncture, and even simple exposure of the kidney by lumbar incision have severally accomplished precisely what has justly been claimed for decapsulation, namely an entire relief of the symptoms, the profession is in the dark as to the precise mechanics of the improvement. Nephropexy has not been inconspicuous in giving relief from hematuria, and, while there are those who have asserted that nervous influence is the principal therapeutic feature in all these operations, Senator is convinced that it is a mere breaking up of adhesions or the fixation of a more or less movable organ which cures. Many have claimed that these good results, especially in a case of nephrotomy, were due to relief of the tension through division of the fibrous capsule. Others contend that the result is obtained by relief of congestion through the establishment of new blood vessels in the adhesions following operation. Operations for the relief of hematuria are still *sub judice*. It is therefore appropriate to relate the following case history: The patient was an Irishman, fifty-nine years old, anemic and emaciated. Twenty years ago he first noted blood in his urine. The hemorrhage was often profuse, the urine being opaque from blood and often thick with clots. For a year previous to the operation he had bled constantly and profusely, so that he had become all but exsanguinated. At various times during the illness pain was felt over the bladder, but none along the ureters or over the kidneys. There were at no time signs of uremia. Internal medication failed absolutely. Segregation showed the bleeding to come from the left kidney alone, the right side being normal. The hemoglobin per cent. was about thirty. The left kidney could not be palpated. No evidence as to the origin of the hemorrhage being detectable, a provisional diagnosis of chronic unilateral interstitial nephritis was made. At operation the kidney, which was normal in size, was shelled out of its adherent fatty capsule and decapsulated. The surface was granular and the fibrous capsule was also adherent. Considerable hemorrhage from the cortex occurred, which was with difficulty checked by prolonged pressure. Recovery was uneventful. The blood vanished from the urine, which became entirely clear within eighteen hours from the time of operation. During the ten weeks which had passed since decapsulation, there had been no signs of hematuria. Analysis shows it to be normal, a condition which had not existed for twenty years, because casts and albumin had been present in great quantities for an indefinite period prior to operation. A piece of the cortex, which was removed during operation showed advanced glomerulo-nephritis, and advanced arteriosclerosis. The author's conclusions are as follows: (1) The prominent cause of renal hematuria, which is often unilateral, is chronic interstitial nephritis, often involving the glomeruli. (2) This, together with other obscure causes must be excluded before a diagnosis of "essential hematuria" can be made. (3) Decapsulation of the kidney is indicated in these cases, as it offers a good prospect for cure of both the hematuria and the nephritis. Nephrectomy should be discarded on account of probable involvement of the other kidney.

THERAPEUTICS.

Improvements in Dietetic Diabetics.—Although many efforts have been made to improve upon the present method of treatment of diabetes, it must be confessed that the dietetic treatment is fundamentally the best at hand. James Sawyer (Brit. Med. Jour., March 5, 1904) states that it has long been recognized by the profession that the decrease in sugar and specific gravity in the urine are almost invariably marked by profound improvement in the general bodily conditions. It has therefore been the effort of many practitioners to make out dietary lists which shall be as little objectionable as possible. Until the researches of Mossé

were published two years ago, it had been the almost universal rule to withhold potato. The potato contains from 16 to 24 per cent. of starch. Mossé has concluded, however, that potatoes, far from being harmful, form a useful and beneficial food in glycosuria and that they are capable of being substituted for ordinary wheat bread in daily proportion sufficient to maintain the alimentary ratio. He found that a daily ingestion of two to three pounds of potatoes effected marked improvement in 19 out of 20 cases of diabetes. Singular to relate, they were instrumental in relieving the thirst. Possibly the potash, which is present in a large quantity in the potato in various combinations, is instrumental in making this tuber such a favorable article of diet. The author considers that the introduction of potato will prove to be the most important therapeutic advance made in late years in the treatment of diabetes. In order to preserve the potash and other salts, it is most essential that the potato should be cooked with its skin on. The author has prepared delicious baked cakes from a paste composed of a kind of flour prepared by rubbing down potatoes cooked with their coats on by steaming, blended with cream and butter. Bread and biscuits of a palatable kind can be made from bran and this potato flour. This seems so practical and useful a step that the details are welcome. They are as follows: Half pound of steamed potatoes, one-quarter pound bran, half an ounce of German yeast, half an ounce of butter, one egg. Twenty-four hours before making the dough, cook the potatoes by steaming them in their jackets, then peel and break up into flour with the fingers. Mix all the ingredients together and let the paste stand by the fire for an hour to rise. Bake for an hour and a half.

Treatment of Anchylostomiasis.—This disease has been shown to be so rife in many of the Southern States, that a consideration of its treatment is a desideratum for all. C. W. BRANCH (Brit. Med. Jour., March 5, 1904) states that it is by no means the experience of those who deal largely with *Anchylostoma*, that, as is stated by Prof. Stockman, they are readily killed by large doses of thymol. The author's routine is to give 30 grains of thymol in powder at 4, 6, 8 and 10 A.M. on an empty stomach followed by one ounce of castor oil at 6 P.M., that is, he uses 120 grains in the first treatment. Smaller doses are known by those who deal largely with this condition to be ineffectual. Even with these large doses, fully half the cases are not absolutely freed from the parasite. This dose of 120 grains of thymol may be given with absolute impunity, regardless of age. Children of three years take it without trouble. It should be noted that if, as is customary, these patients are coincidentally put on iron tonics, they will at once begin to improve with the disappearance of the anemia, whether or not the worms have entirely been cleared out of the intestinal tract. The practitioner must not be deceived by this improvement, which will be found to depend entirely upon the iron and which will cease after the worms begin reproducing in numbers, as they will, unless thoroughly killed and eradicated.

Treatment of Basedow's Disease.—The milk of goats deprived of their thyroid gland has given excellent results in Basedow's disease, but most patients cannot bear its prolonged use. As substitute, W. KUHNEMANN (Münch. med. Woch., March 8, 1904) recommends rodagen, a preparation obtained by precipitating the milk with alcohol To insure himself that the improvement really came from the drug, the author ceased giving it, when the pulse-frequency again rose and the patient lost in body-weight.

Lumbar Puncture in Uremia.—The astonishing statement is made by A. SEIFFERT (Münch. med. Woch., March 8, 1904) that most cases of uremia complicating scarlet fever can be cured if treated by lumbar puncture. The technic is very simple: the patient is simply placed in the lateral position and punctured between the twelfth dorsal and the first lumbar vertebræ; as soon as the fluid appears, 5 to 30 grams are aspirated by means of a syringe. The initial and ofttime fatal convulsions of scarlet fever and measles also yield readily to lumbar puncture and a trial in purely renal conditions and in eclampsia is certainly indicated.

Influence of Dog Serum on Experimental Tuberculosis.—Despite the fact that the dog is exposed to tuberculosis more than most other animals, cases of infection are only rarely seen by veterinary surgeons, probably because some natural immune bodies are present in the serum. This observation has stimulated R. LINK (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) to try the effects of injections of dog serum upon rabbits experimentally inoculated with tuberculosis. In every case parallel experiments were made and the eye was generally selected for inoculation, as here the development of the lesions could be best observed. The results are rather discouraging since a favorable influence could not be absolutely proven, though in a few cases the disease seemed to run a milder course. The nodules on the iris occasionally showed a tendency to heal and at the post-mortem examination fewer tubercles were found in the organs, but an active immunization was never seen.

The Action of Organic Iodine.—The principal desiderata in iodine compounds for internal medication are: the presence of iodine in sufficient quantity to be productive of physiological effect, the absence of irritating properties, assimilability and the absence of other chemical compounds which might directly or remotely interfere with the action of the iodine. G. F. LYDSTON (Medicine, March, 1904) claims that these desiderata are all to be found in the organic preparation of iodine known as iodo-nucleoid. He found by experience that it was non-irritating and readily assimilated. It was less likely to produce iodism than the other salts of iodine, and being perfectly stable, could be administered in pill or powder form. While he is not prepared to state that it fills the rôle of iodide of potassium in every instance, he believes that in many cases which are intractable to the action of iodide of potash, excellent results are obtained from the iodo-nucleoid. Experiments were also made to determine whether more iodine could be retained in the body from the potassium iodide or from the iodo-nucleoid. It was found that 8 per cent. of iodine was retained from the potassium iodide, and 64 per cent. from the iodo-nucleoid.

Subcutaneous Feeding.—The subject of subcutaneous introduction of food has been a very unsatisfactory one, for hitherto only sterilized oil proved suitable. Kalodal, a proteid obtained from meat has been extensively tried by D. CREDÉ (Münch. med. Woch., March 1, 1904) and seems to be eminently suitable before and after operations in weakened individuals, since it can be sterilized and is not followed by pain or albuminuria. Instead of giving a plain infusion of saline solution the author now invariably adds five grams of kalodal in 500 grams of fluid, which he introduces under the skin at two different sites. This can be repeated every six hours, so that the patient receives twenty grams of albumin or 82 calories subcutaneously every day. Since a cachectic individual requires only about 27 grams, the advantages are evident. If an attempt is made to concentrate the solution, small amounts of albumin will appear in the urine but the amount can be considerably increased by adding kalodal to nutritive enemas, as it is very rapidly absorbed from the rectum. The drug is on the market in sterile solution in glass tubes.

INFANT MORTALITY AND FOUNDLING CARE.

Our editorial in the Medical News of March 26, "The Decrease of Foundling Mortality" has brought to us a number of requests for more definite information with regard to the possible increase of infant mortality in New York city in the families of those who after the death of their own child adopt foundlings. We are glad to find that there is so much interest in this important subject. We are sorry that we cannot give definite statistics in the matter, since as it is easy to understand, a special investigation over a wide field would have to be carried out in order to furnish them. The only data for our declarations in the matter are the opinions of physicians whose attention has been called to the subject by their experience in such families, but who are quite positive in their assertions that there is room for more than suspicion with regard to the high infant mortality that obtains.

It might seem utterly lacking in all faith in human nature to attempt to demonstrate that mothers should neglect their own children to such an extent as to cause an increased mortality among them simply for the purpose of being enabled thus to add to the family income by adopting a foundling. The investigations of several Parliamentary committees in England and, we believe, also of one public health department investigation in France, has shown, however, that whenever the life insurance of infants is allowed, infantile mortality increases among the insured. Not that there is actual direct doing to death of the children under these circumstances, but that there is a more or less unconscious neglect of a number of precautions necessary to maintain the child's health, and above all, when the child is suffering from serious illness a certain failure to supply that self-sacrificing devotion which is so necessary to preserve the life, particularly of a delicate child, when death threatens and only unceasing care can avail. Mothers probably do not quite realize what tempts them to be somewhat less careful of their children than they otherwise would be, but the temptation is there and the effect is to be seen in the mortality lists.

There is another phase of the question that seems worth calling to public attention at the same time. There is no doubt now that in the hands of midwives the infant mortality among new-born children in the foreign populations of New York city is appallingly high. It has been said over and over again that we cannot get along without the midwife, since many of our foreign born population will not employ regular male physicians and since, besides, there is often not sufficient money to pay properly for the services of a regular physician. The immense infant mortality that occurs under midwives' care might, it would seem, keep mothers from employing them as much as is now the case, for, after all, it is not a difficult matter in almost any part of New York city to secure through one of the many charitable organizations the services of a physician without charge.

One reason why this high mortality among children delivered by midwives seems not to deter many mothers from employing such help in labor is the feeling that even if their child does die there will be the compensation of having the opportunity to adopt a foundling, and thus add materially to the family income. After all, it must not be forgotten that $10 or $12 a month, when the only wage earner is obtaining less than $50 a month, is a very important addition to the means of a family. It is even more than might be the single $50 or $60 that would be obtained as insurance for a dead child. To some doctors it has even seemed that sufficiently long efforts were not made to resuscitate apparently dead stillborn children, because of the fact that a dead-born child is not under these circumstances so

serious a misfortune as it is under ordinary conditions.

Such consideration may seem far-fetched, but human motives are wonderfully complex, and sociological studies serve only to show what apparently trivial factors may tend to swing the balance of human action along particular lines. It is with the idea of calling attention to this subject as a field for investigation on the part of the charitably inclined, who are at the same time interested in sociological problems, rather than definitely to accuse present conditions that we entered upon the discussion of this subject. We have no doubt at all that there is more in it than has usually been considered, and we would welcome contributions from physicians whose experience seems to show that present conditions in the decrease of foundling mortality are not so entirely without their compensating evils as has sometimes been thought. We may say that we expect to publish some articles dealing with this aspect of medical work among the poor of large cities before long.

"IN HOC SIGNO."

Not only by the precepts learned at our grandmother's knee, but by the teaching of our great medical authorities do most of us believe that a scarlatina patient who is "peeling," is a chap to be avoided. If this fond belief is to be torn up and taken from us, the sooner it is done the better.

That we are, the world over, agreed as to the danger of scarlatinal scales can be inferred from the following quotation from Osler:

"When desquamation begins, the child should be thoroughly rubbed every day or every second day with sweet oil or carbolated vaseline, or a five-per-cent. hydro-naphthol soap, which prevents the drying and the diffusion of scales." Holt—Diseases of Infancy and Childhood, states that: "Even the mildest cases should be isolated for four weeks, and all cases until desquamation is complete."

So thoroughly is this idea of the infectiousness of the scales engrafted upon the professional mind, that the picture of unfortunate adults who, failing to peel propitiously, have as a consequence been incarcerated for six or seven weeks, is not uncommon. There they sit in their solitary pens slowly and painfully grinding the refractory skin from their soles and from the palms of their hands with a block of pumice! It makes one think of Booth's memorable picture of Shylock whetting his knife upon his sole. If the undesirability of this enforced confinement is objectionable from the standpoint of expense to the community, how infinitely more is it so from that of offence against the individual! Grinding one's sole down with pumice stone seems to be more a desideratum for the complaining moralist than for the practitioner of medicine.

R. E. Lauder, Medical Superintendent of the Borough and Port Fever Hospital of Southampton, England, who has had a vast range of experience in the treatment of scarlet fever, states, in the *Lancet* of March 12, 1904, that as a result of careful observations and studies bearing upon the etiology of the so-called "return" cases, he became a year ago thoroughly convinced, theoretically at least, that he was working from a fallacious standpoint. He therefore determined to alter the entire policy of the hospital which bore on prophylaxis. Needless to say this had in the past been carried out under the assumption that desquamation was the prime factor in determining non-infectiousness of the convalescents.

The Southampton Isolation Hospital is a refuge not alone for the Port, but also for a broad territory in and about the city. So many patients who from a basis of "desquamation" had been discharged as absolutely harmless, had without any doubt infected others after their dismissal, that in this hospital, as well as in many others throughout the world, complaint was being freely made that the so-called "isolation" provided by them was not of sufficient value to compensate the public for the support of maintaining these institutions. If the conclusions reached purely as a result of these agitations result in the establishment of an entirely new basis of protection giving, it will at least show the value of adverse criticism. The new methods adopted are as follows: Before removal from the ambulance, each patient is carefully examined and undoubted cases of scarlatina are put into an "acute room," being kept there until the acute stage of the disease is passed and diphtheria has been excluded by bacteriological examination. At the end of the third week of the disease, if free from complications, patients are transferred from the general ward to another pavilion, which has been thoroughly disinfected. Here they are kept for one week, noses and throats being douched daily. At the end of this time, viz., in the fourth week of the disease, they are discharged from the hospital,

no matter what the condition of desquamation may be.

The tabulated forms show the following results: In 1892, 208 cases were removed to the hospital; 164 were discharged. Their average stay was forty-eight days. The number causing "return" cases was seven. In 1903, 353 cases were removed to the hospital; 325 were discharged; thirty-four days was the average stay, and the number causing "return" cases was seven. In other words, in 1902, the percentage causing "return" cases was 4.27. In 1903 it was 2.15. The percentage after forty-eight days' treatment was almost double that which followed thirty-four days' treatment.

Thus it appears that prolonged stay in the hospital and absence of desquamation do not assist in preventing "return" cases but actually seem to favor them. That the respiratory tract rather than the dry scales, which are thought by the author to be but the harmless products of toxic elements, is the responsible focus of infection is substantiated by the observation that evidences of infection often follow operation on the upper respiratory tract. Furthermore, constitutional symptoms and fever are as a rule proportionate to the condition of the respiratory passages and a great majority of return cases is associated with a history of contact with a convalescent suffering from upper respiratory discharges.

In view of the apparent difficulties hedged about the building of suitable isolation hospitals in this city, it may be interesting, if true, to note that this new basis of prophylaxis, if instituted, would increase the existing hospital facilities by about one-third.

CIRRHOSIS OF THE STOMACH.

It must now be admitted that the evidence upon which Andral, Cruveilhier, Brinton, Wilkes and others sought to establish differential points between diffuse carcinoma of the stomach and benign cirrhosis, was imperfect. Of late years the condition has been given abstract or more or less academic recognition, but no definite effort to base differential diagnosis of the two conditions in the light of modern gastric pathology has yet been brought to a focus. Osler recognizes the condition and reports a particularly characteristic state. Einhorn says that a benign cirrhosis does occur. Hemmeter writes that the pylorus may be the seat of a hypertrophic stenosis and that in rare instances the entire stomach may be involved in this process. German pathologists give little attention to the condition. The French pathologists, Bret and Caviot, maintain a negative attitude. Most Continental writers in general agree that the condition looked upon by the English-speaking pathologists as benign cirrhosis is in reality an evidence of low grade malignant change. This belief they base upon the fact that although no evidence of carcinoma is to be found in the wall of the stomach, the lymphatic glands draining the organ show signs of involvment.

The *Annals of Surgery*, March, 1904, contains a monograph by John G. Sheldon on the subject which is as rich in bibliographical details as it is in original suggestions. There are so many people wandering about the country, utter physical wrecks, traveling hopelessly from local practitioner to town practitioner, thence to the specialist of the neighboring city and finally to the well-known investigator of gastric lesions in some great University center, gaining nothing but hardship, losing hope and strength, a blight upon and a menace to the medical profession at large, that it is expedient to have all progress made in the rational treatment of these cases scattered as broadly as possible among the general practitioners of medicine. The case detailed by Sheldon went through exactly this itinerary, except that the final brilliant cure is repeated in but a small proportion.

Because of these facts; First, that such cases are common; second, that under medical treatment they obviously can obtain no relief; third, because of the just opprobrium which comes to the profession through its inability to cope with them, the details of Sheldon's case are well worthy of quoting.

The man under consideration was fifty-two years of age. He was perfectly well until fifteen years ago. From that time, his symptoms can be divided into four periods. For the first six years, he was troubled with sourness of the stomach, poor appetite, dull pain, belching of gas and a coated tongue. These symptoms slowly progressed. At the end of the sixth year he felt well only at short intervals. During the next four years, from his forty-fifth to his forty-ninth year, his symptoms gradually became more severe, but he continued to work on his farm. During these eleven years of suffering he had received no treatment. Neither had he taken medicine of any kind. During the last three years of his illness he was unable to work on account of weakness and suffering. Abdominal pain was nearly

always present. It was sometimes dull and gnawing, at other times the paroxysms were so severe as to require morphine. The pain was always in the median line of the abdomen above the umbilicus. It was never located in a small area and never radiated. Ingestion of solids or liquids increased its severity. Vomiting sometimes gave partial relief. Next to pain, it was his most distressing symptom. Sometimes it occurred immediately after eating, sometimes not before two or three hours. He often vomited food that he had eaten forty-eight hours before. His appetite was always good till the last year of his illness.

In one of the great eastern cities, a diagnosis of gastric ulcer was made and rectal feeding resorted to for three weeks. During this time he improved. On returning home, he began to eat and the old symptoms returned.

Physical examination was negative. Laboratory examination showed the gastric contents to yield no hydrochloric acid. The red cells were 2,800,000, the hemoglobin 48 per cent. Inflation of the stomach was puzzling. Its outline could not be determined by external examination. On operation, the stomach wall was found to be at least one centimeter in thickness. It cut with resistance and the cut surface looked like fibrous tissue. The gastric mucosa was smooth and atrophic. A Murphy button was used to perform gastro-enterostomy.

Three months after the operation this patient had gained 36 pounds. Enough time has now elapsed to positively exclude the presence of malignant growth, no evidence of which could be found at the time of operation. There is therefore no other alternative than to believe the lesion to have been a benign cirrhosis.

The etiology of this condition is only vaguely known, because not more than ten cases have been recorded with any degree of definiteness. The average age is about fifty years. Men and women are equally affected. Alcohol does not seem to play an important part in the causation of the disease. Ordinarily it is unassociated with other diseased conditions, cicatricial changes in the liver, spleen or kidneys not having been mentioned in any case. The symptoms have in general been those of long standing and obstinate dyspepsia. Physical examination was found negative in all but one case. In this instance a movable tumor was discovered in the region of the stomach which proved to be a conglomeration of non-malignant tissue due to trauma.

Sheldon concludes that the following conditions would point to the diagnosis of gastric cirrhosis: (1) Long standing disease (2) absence of vomiting of blood; (3) a contracted stomach; (4) absence of a tumor on palpation; (5) absence of glandular or hepatic involvement; (6) improvement of the patient generally and relief of the stomach symptoms for a considerable period of time when rectal feeding is resorted to. Obviously the treatment indicated is gastro-enterostomy.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—The Section on Medicine will hold a meeting Tuesday evening, April 19, at 8:15 o'clock. Following is the program: I. Presentation of Cases. II. Clinical Reports: (1) Tabes with Early Appearance of Charcot Joint, with exhibition of patient, by W. B. Noyes, M.D.; (2) Myxedema, with exhibition of patient, by H. S. Patterson, M.D.; (3) Typhoid Fever with Repeated Chills, by John Howland, M.D. III. Papers: (1) The Isle of Man as a Climatic Station, by James K. Crook, M.D.; (2) Who is Underfed? by Heinrich Stern, M.D.

Health Department Appointment.—Dr. John A. McCorkle, of Brooklyn, was chosen last week by Health Commissioner Darlington as a member of the advisory board to the Health Department. The position is honorary.

Dr. Lederle's New Venture.—Dr. Ernst J. Lederle, Health Commisisoner in Mayor Low's administration, has established a laboratory for sanitary, chemical, and bacteriological investigations. Associated with him are Joseph A. Deghuee, Ph.D., and R. C. W. Wadsworth, his secretary while health commissioner.

Reception to Dr. Paul Ehrlich.—Last Saturday a reception was given to Dr. Paul Ehrlich by Dr. S. J. Meltzer, which was attended by a large number of distinguished scientists from New York, Boston, Philadelphia, Chicago, Montreal and other cities. Coming at the close of the session of the Association of Pathologists and Bacteriologists, many members of this body, coming from over the entire United States, were present. This gave the gathering a particularly cosmopolitan aspect.

Home for Incurables.—The will of Julie F. H. Nevins, filed last week in the Surrogate's Court, leaves $1,000,000 to build and maintain a home for the aged. The proposed institution is to be known as the "Henry Coffin Nevins Home." The trustees are the Central Realty Bond and Trust Company, Smith Mason, and Miss Ida Mason, Joseph Neuscheler, and Charles Strauss. Mr. Strauss said that no definite steps had yet been taken toward carrying out Mrs. Nevin's plans. It would take some time to get the trust into shape, and meantime the trustees were considering sites. He could not say whether the home would be established within the city limits or in the country. It will accommodate 100 persons.

Hospital Appointments.—The following men at the College of Physicians and Surgeons received appointments during the past week as follows: Lying-in, C. T. Stevens; R. N. Prentiss, M.D., 3rd year; M. D. Thomas; C. E. McNenney. The S. R. Smith Infirmary, C. A. Holmes. The J. Hood Wright,

R. H. Breed; H. N. Moeller; W. C. Bartrum. Paterson General, E. D. Royall. Roosevelt, A. M. Clark; B. W. Paddock; F. D. H. Coerr; J. C. Dingman; T. L. Saunders; J. S. Thomas; A. Van der Veer, Jr.; P. H. Ringer. New York, 1st, Edward Cussler; James Greenway; W. Gillespie, M.D., P. & S., 1903; H. W. Lathrop; W. F. Burrows.

Resolutions on the Death of Dr. John Metcalfe Polk.—At a special meeting of the Class of 1899 of the Cornell University Medical College, held April 4, 1904, the following resolutions were unanimously adopted:

Whereas, we have learned with deep regret of the death of our classmate, John Metcalfe Polk, M.D.;

Resolved, that in the death of Dr. Polk the class of 1899 loses one of its most promising members, and that the medical profession is deprived of one whose career opened with unusual brilliancy.

Resolved, that we tender to the family of our late fellow-student our heart-felt sympathy in their great bereavement.

Resolved, that a copy of these resolutions be forwarded to the family of our deceased classmate, and that they be sent for publication to the medical journals of this city and to the *Cornell Alumni News*. Frederick L. Keays, R. J. E. Scott, William J. Jones, *Committee*.

Basilar Meningitis.—There have been a number of cases of acute cerebrospinal meningitis in this city during the past month and some have gone so far as to declare it an epidemic which is, however, at the present writing far from the truth. At the Health Department on April 8th it was said that, while the number of cases of meningitis did not warrant the statement that it is epidemic among children, there has been a marked increase in the number of cases, many of which have proved fatal. For the week ending April 2, there were 31 deaths reported for this disease, and for the week previous, 26. By far the greater number are in Manhattan, and the deaths for a month in that borough indicate how rapidly the disease has spread. During the first week in March there were 6 deaths, in the second 13, in the third 10, and in the fourth 24.

The Alumni Association of St. Luke's Hospital.—On April 8, 1904, this society held a meeting. A paper on radium was presented by Dr. Robert Abbe, who also showed specimens of radium obtained from the Curies in Paris and from Germany, and demonstrated the Piffard ultraviolet light. The Austrians have cornered the market on radium and the Curies have no more for sale, but Dr. Abbe showed the plates of experiments by which he was able to prove that the Austrian product of 1,000,000 strength was not so strong as the Curies' 300,000 specimen. That the luminosity is no indication of the chemical activity was also well shown by a series of plates. Many experiments have been made by the speaker, and he has found that *Amœbæ* and other protozoa are much affected by the rays, that ant larvæ, though not killed, were prevented from developing, and, as had been shown by others, that moth larvæ failed to develop into adult moths, but continued to live an exceptional length of time as larvæ. Bacteria are very little affected. Dr. Abbe has used radium in a number of cases of lupus and epithelioma of the face and jaw, and cancer of the breast. He was able to report remarkable success in several of these, and showed photographs and casts taken at regular intervals. One noteworthy case was an epithelioma of the lower jaw, another was a recurrent cancer involving the whole left breast. In the latter case, casts and photographs were made every six weeks, and they graphically showed the marvellous and progressive dwindling of the neoplastic tissue. He was not able to say that the radium emanations would penetrate far into the tissues, for he had found that the insertion of radium beneath the skin of a rabbit had absolutely no effect, while the same radium placed on the skin would cause a dermatitis. In the treatment of superficial new growths, he would place the knife first, then the X-rays, and after that, radium.

Dr. Charles T. Dade said that at the skin department of the Vanderbilt Clinic the use of radium had been abandoned. In epithelioma of the face it had no effect on the pearly border, and a curetted area healed more rapidly than another area exposed a great many times to radium. It had also failed in lupus vulgaris and in lupus erythematosus.

Dr. F. S. Meara spoke of the remarkable similarity of the phenomena produced by two entirely different physical forces, the X-ray being a species of ether waves, while the radium effect is produced by actual particles of the radium which are hurled into space. They are much smaller than atoms and theoretically can pass through the human body with ease.

Dr. J. E. Traub reported some experiments done with Dr. Sinclair Tousey with radio-active solutions. Some of these have already been reported by Dr. Tousey. A dog given radio-active saline infusions intravenously showed no change in general health or in blood pressure. Fluorescein solutions placed in the stomach gave a very clear picture of the borders of the organ when an electric lamp was inserted. In making radio-active solutions an open tube must be employed.

The Cat Nuisance.—In view of the proposed changes regarding the licensing of certain domestic animals in this city it may be well to speak a word as to the need for such legislation. Nearly everyone has had something to say upon the question of allowing dogs in the streets and public buildings, but cats have so far escaped the attention that is certainly their due. Through our dog muzzling ordinances we have succeeded in enlisting the strong arm of the law against disease, as it is transferred from the canine to the human species in the form of hydrophobia; but attention is now called to the fact that cats also are sometimes a source of conveyance of specific microorganisms. Although this may be a rather rare circumstance its possibility must be admitted by all, and the reporter happens to know of two cases where diphtheria was carried from one house to another by an immune feline whose responsibility was directly and absolutely proven when it was too late to save the child to whom the bacilli were thus conveyed. There is, however, one phase of the question which though not immediately dangerous to public health is certainly very annoying, and that is the various maneuvers which these animals go through in securing for themselves the removal of waste products of metabolism and in carrying on the reproductive function. This matter has been for some time a favorite subject for non-pet-loving individuals in their letters to the daily press, but nothing has come of it save a harmless bit of humor now and then, and the satisfaction that "constant reader" derives from seeing his philanthropic and finer thoughts in print. There is certainly enough proof of this condition of things even for the most bigoted anti-vivisection or anti-ordinance devotee; for it is only necessary to stroll about the walks, particularly those in the vicinity of the parks, to obtain evidence that must be convincing. Just at

present, however, one's attention is being strongly directed to the night orgies of promiscuous bands of cats in the neighborhood of his bedroom window. It would seem that the oft-quoted bit of verse, "in the spring a young man's fancy, etc.," is most reprehensibly applicable to the feline species at this season; at any rate, one who cannot sleep during the day is to be wofully pitied. The yowlings of these "pets" probably simulate a human cry more closely than the outcries of any other animal, and when constantly keyed up to the highest pitch from 10 P.M. until 4 A.M. life becomes indeed a responsible thing. Now the law recognizes the right of every citizen to as much calm and repose as he can possibly find in a great city, and it also recognizes that he may and can have grievances against unnecessary nuisances, both public and private. To be sure there are the flat-wheeled car and the old clothes man and the street gamin with his terrifying whistle, but these are noises heard mostly during the day and are in a measure unavoidable in our cosmopolitan life; in any case one can become accustomed to them in time through what the psychologists call a "laudable deafness," or something of the sort. But can one ever become accustomed to the nerve-torturing howls of a cat, to say nothing of a half dozen cats all vociferating at once? Perhaps so, but never as long as his sensorium remains in normal condition. The reporter would enjoy bringing to justice the person who first imported cats in New York city, no matter how praiseworthy his purpose, and it is not difficult to see how Dante would have pictured such a one in the Inferno. One rarely sees mice where cats abound. Perhaps the rodents are frightened away by the soul-piercing mewlings; certainly nobody has ever reported the killing of a mouse by a cat of the New York variety. To sum up, then, there is no reason for the existence of cats in this city, and if it can be proven that they serve any purpose whatever, useful or ornamental, there is still no reason why they should enjoy absolute lack of restraint, day or night, and absolutely no reason for their monopoly in setting in motion waves of unknown amplitude and greater possible vibration.

PHILADELPHIA.

Dr. Faure Entertained.—A reception and luncheon were tendered at the Woman's Hospital, April 8, to Dr. J. L. Faure, a distinguished French surgeon, and Dr. Howard A. Kelly, of Baltimore. Dr. Faure is visiting many institutions of this country in an investigation of American surgical methods. In a short address he spoke very highly of the proficiency of women physicians in this country and deplored the fact that no such opportunities for the study of medicine were afforded the women of France.

Typhoid Record Broken.—During the past week the new cases of typhoid fever numbered 389, the largest number reported in seven days in the history of the city. Deaths were twenty. Health officials are of the opinion that the epidemic has reached its height and will from this time on decline unless new freshets again stir up the Schuylkill. The only remedy offered is to boil the water.

Pasteur Institute Needed.—City Veterinarian Hartman, while discussing the recent large number of bites by dogs, affirmed that one of Philadelphia's most urgent needs is an institute for the treatment of persons who have been bitten by rabid dogs. He asserts that the Pasteur method could be carried out by the Board of Health at comparatively little cost. A hospital is not needed, simply a place for the manufacture and application of the virus.

Individual Communion Cups.—Dr. Howard S. Anders, in an open letter to the *Ledger*, comments very pertinently on the recent action of Bishop Fowler in refusing to administer the memorial of the Lord's Supper at a conference because individual communion cups had been provided. He states that the general principles of cleanliness, sanitary safety and delicate consideration for others are now so generally in use that it is unusual to meet with such petty and untimely objections. Since the inception of the reform "it has won its way, quietly, educationally, more and more widely among the congregations of various churches of the principal denominations, from a mere handful of about a score in 1894 to over 2,000 in the United States alone at the present time. This shows that the innovation has come to stay; that the people are deciding in favor of it; that sensible pastors sanction it; that the authority of bishops cannot retard it. Nearly every week a church somewhere adopts the individual communion cup method of administering the wine for the first time; and no church reverts to the single cup again."

A Case of Galactocele.—A case of this uncommon condition was reported at the Philadelphia Academy of Surgery, April 4, by Dr. W. W. Keen. He stated that he had amputated the breast at least 500 times and had seen from 300 to 500 more cases that did not require operation; among them all this was the only case of galactocele. The patient was a colored woman of twenty-one years who was married at the age of eighteen years. She had had one miscarriage and was later delivered of a full-term child which is now nine months old. She states that she noticed a small lump in her left breast when she was twelve or thirteen years old; this began to increase in size when she was three months pregnant. At the time of operation one-half of the breast was involved. The entire breast was removed, this being considered the proper treatment for such cases. Examination of the specimen showed it to contain one large and many small cysts that were filled with milk of an almost semisolid consistency. Microscopic sections revealed the presence of a conspicuous round-cell infiltration of the mammary tissue that justified the diagnosis of acute non-suppurative interstitial mastitis in addition to that of galactocele.

CHICAGO.

To Wage War on Tuberculosis.—Dr. Geo. W. Webster, President of the Illinois State Board of Health, recently addressed the Progressive Health Club on tuberculosis, and among other things he said: "I have with me a set of statistical tables just completed by the State Board of Health, showing that the number of deaths in Illinois from consumption during the year 1903 was 7,026, while pneumonia claimed nearly as many, 6,830. The greatest source of infection from consumption is through the medium of the sputum, and if the sputum of every consumptive could be destroyed, the disease could be banished from the face of the earth. Experience has shown consumption is a preventable disease, and in 70 per cent. of the cases, a curable one, if taken in time. What is needed in every State in the Union is a sanatorium for the treatment of consumptives. The stamping out of this dread disease is a matter for education and evolution. It depends upon right living, cleanliness, sunlight, temperance, good food, fresh air, and proper care."

Dangers of May Moving.—Physicians in this city during the last three or four years have been investigating a phase of the house-cleaning situation which ought to be more generally understood. It has been discovered in a great number of instances that a thor-

ough cleaning, disturbing, as it does, in many cases the accumulated dust and dormant germs of years, is followed almost immediately by the development of sickness in the family, undoubtedly brought about by the new activity of these germs. Physicians are cautioning their friends at this season of the year, either if they are moving into new apartments or continuing in their old ones, to see that a thorough fumigation of every room goes on, in addition to the cleaning, before the home is occupied. The wisdom of this course, particularly when a family moves into a flat previously occupied by people whose physical condition and surroundings are utterly unknown, is apparent at the first glance. There is a movement now on foot among some of the leading medical men of the city for the preparation of an ordinance that shall make it compulsory on the part of a landlord to thoroughly fumigate a vacated apartment to the satisfaction of the Health Commissioner before it is offered for rent to a new comer.

First Aid Instruction to Employees.—The management of the Pennsylvania System has decided to instruct all the employees of the operating department in rendering first aid to the injured. The plan will soon be put into effect on the lines in the East and West, thereby covering the entire system. The plan is comprehensive, and includes equipping all baggage, mail, express, working and wrecking cars, terminals, yards, offices, shops and important stations with stretchers. The so-called first aid boxes will also be provided in all locomotives, terminals, yard offices, shops and stations. These boxes will contain six sterilized first aid packages. Each package contains one large triangular bandage, one ordinary roller bandage, two compresses and two safety pins. No drugs or liquors will be provided. The boxes will be of wood, and will contain a tin box, in which the materials will be confined. The Pennsylvania is also perfecting plans for the construction of several hospital cars adapted for the transportation of the sick, and to be used in emergency cases.

Establishment of Antitoxin Stations.—Thirty-six diphtheria antitoxin stations have been established in various localities throughout the city, at which physicians may obtain antitoxin free for indigent patients, and at low rates for those able to pay. Culture outfits may also be obtained at these stations.

Resignation of Dr. Kreider.—Dr. Geo. N. Kreider, of Springfield, Ill., Major and Surgeon, assigned to the Fifth Infantry of the Illinois National Guard, has resigned, and Dr. Arthur F. Wilhelmj, of Decatur, has been designated to fill the vacancy on the examining board of the regiment, caused by the resignation of Dr. Kreider.

The Influence of Alcohol, Ether and Chloroform on Natural Immunity in its Relation to Leucocytosis and Phagocytosis.—Dr. Geo. Rubin presented a paper on this subject before the March meeting of the Chicago Pathological Society. He divided his work in three series, namely, alcohol, ether and chloroform. He found that all of these narcotics lower the resistance of rabbits to infection, and that it makes no difference how the narcotic is administered, hypodermically or by inhalation, so that the necessary amount is absorbed to produce complete narcosis. The author found that in the rabbits narcotized and infected, the leucocytosis was considerably lessened, and the animals often succumbed to the infection, while the controls had marked leucocytosis and recovered. In those cases where both rabbits died, the control usually survived his narcotized fellow for a considerable period of time. In certain cases the discrepancies in the leucocyte counts were not sufficient to account for the recovery of the control rabbit and the death of the other. So he reasoned from that, that the narcotics may have an unfavorable effect on the functions of the phagocytes. To test that presumption the author carried out several experiments which were as follows: Two rabbits were injected intraperitoneally with an emulsion of carmine, one having been previously narcotized. He found that a greater number of phagocytes took up carmine granules in the control rabbit than in the one that was narcotized. He also demonstrated a negative chemotaxis between alcohol and the leucocytes. He inserted two capillary tubes, one filled with alcohol, the other with bouillon, under the skin in rabbit's ear; when withdrawn twenty-four hours hence, he found that the bouillon tube was filled with leucocytes, while the alcohol tube was empty. The author gives tables of leucocyte counts made from the blood of 60 drunkards, which show a marked reduction in their number. Differential counts in 25 cases show no deviation from the normal ratio. He found also a considerable difference in the number of leucocytes in the steady and periodical drinker. The latter has more leucocytes than the former. He tries to explain this phenomenon in two ways: (1) That the alcohol may have a detrimental effect on the leucocytogenic centers, so that the tissues in the periodical drunkard have a chance to recuperate between the periods of intoxication, while in the steady drinker, the tissues being constantly under the influence of the alcohol cannot produce the normal number of leucocytes. (2) The negative chemotaxis prevents the white blood corpuscles from entering the circulation in as large numbers where there is alcohol constantly present in the system, while in the periodical drunkard the toxic agent is, at times, entirely eliminated. He draws the following conclusions from his work: (1) That alcohol, ether and chloroform have a decidedly detrimental influence on the natural defence against infection, and that this lowering or suspension of the resisting power of the animal is not due to any organic lesions, since no changes in any of the vital organs were discoverable in any of the animals except such as were caused by the infectious material employed. (2) The influence of the narcotics appear to affect directly the substance or substances which inhibit the growth and toxic action of bacteria in the normal animal; and that these substances are either the leucocytes themselves or something derived from them. (3) The period of detrimental action of the narcotic depends largely on the amount administered, the depth of narcosis, and upon the rapidity of its elimination from the system.

When to Operate and When Not to Operate on the Mastoid Bone.—At the March meeting of the Chicago Laryngological and Climatological Society, Dr. Henry Gradle, in a paper on this subject, said that the operative exposure of the cells within the mastoid process is at present fully recognized as a life-saving operation. The literature of the last decade yields annually reports of some hundreds of cases of intracranial complications and of pyemia or otitic origin. Of these cases, inevitably doomed without operation, a variable, but large, proportion is saved surgically. The review of these reports teaches, first, that suppuration of the middle ear, both acute or chronic, involves danger to life. Secondly, that even in the desperate cases thus reported greater success attends mastoid operations, although many of them must extend into the cranial cavity, and, thirdly, that properly timed surgical intervention would have prevented this serious extension of the disease. But on the other hand, it was known that acute mastoiditis gets well in most instances, and kills in very few without operation. While chronic mastoid disease ends perhaps but rarely in recovery without operation, it can and does remain sta-

tionary and unprogressive in the preponderance of patients. There are no reliable statistics regarding the fatality of suppuration of the middle ear and of the antrum not treated by operation. The figures of clinics are not decisive, because they contain a selection of the graver cases. As far as he can estimate from personal experience and available reports published, the fatality of all otitic suppuration, acute and chronic, is in the neighborhood of one-half per cent. The danger is greatest during the exacerbations of chronic suppurations of the middle ear. The mortality of simple opening of the mastoid process fluctuates in recent reports between four per cent. and nearly zero. The radical mastoid operation is generally attended by about eight per cent. mortality. In the statistics of the Illinois Eye and Ear Infirmary for five years of the work done by all attending surgeons, kindly furnished him by Dr. Pierce, 26 simple operations (opening into the mastoid) resulted in two deaths, while in 126 radical operations there were 12 fatalities. He said the indications for opening the mastoid for acute disease can be best defined on the basis of a brief review of the various modes of termination of acute mastoiditis. In at least one-third of all instances acute mastoiditis subsides gradually after a climax of three or four days, provided there is free drainage from the middle ear.

Operative Indications.—(1) The least suspicion of intracranial extension based on persistent one-sided headache or on any cerebral symptoms gives an immediate vital indication. (2) Whenever a perforation threatens, this should be anticipated by operation, and if it has opened spontaneously, through a narrow fistula, the danger of pus under tension should be obviated by better drainage. Perforation is inevitable whenever the posterior wall of the meatus of the ear begins to sag, whenever the soft tissues behind the ear show inflammatory infiltration (not merely a pale edema), or when infiltration begins around and beneath the tip of the mastoid. (3) When the characteristic signs of mastoiditis, namely, pain and tenderness, continue to increase after the third day, or even increase rapidly after the second day, immediate operation is the safest course. (4) When the discharge of acute otitis with mastoid symptoms does not diminish at all in the course of about two weeks of appropriate treatment, chronicity must be expected, even though the mastoid signs diminish. Hence, an operation is now proper. (5) If the mastoid pain and tenderness begin to diminish after two or three days of climax, the operation may be deferred. Those cases in which the mastoid symptoms remain stationary after the first two or three days belong to the debatable class in which it is difficult to say whether to operate or to wait. If mastoiditis follows otitis, the discharge of which has ceased, the need of operation is greater than when there is still discharge from the middle ear. Streptococcus infection means greater danger and more need of operation than the presence of the pneumococcus or staphylococcus in the pus of the middle ear. In cases of doubt an unnecessary operation may be safer than any unreasonable delay. In all acute cases the only operation to be considered is the opening of the mastoid. The radical operation is entirely uncalled-for and improper. In chronic disease of the middle ear and mastoid, the operative indications are to be regarded from a different point of view from those in acute cases. A simple opening of the mastoid antrum, although often curative, is generally not the proper operation. In most cases a cure is obtained quicker and with greater certainty by the radical operation, which converts the antrum, the attic and the middle ear proper into one continuous and accessible space with exenteration of contents. Perhaps the most convenient way of defining the operative indications in chronic disease of the middle ear is to eliminate those cases which do not require operation. It is not proper to resort to operation in the absence of any urgent symptom, until a thorough trial has been given to non-operative treatment. Only after chronic otitic suppuration without urgent symptoms has resisted all conservative methods or has relaxed repeatedly in spite of apparent cure, should the radical operation be considered. If, after such treatment has been properly tested for a sufficient length of time, there remains a discharge free from odor, danger to the patient is not greater and probably less from the disease than from the radical operation. If, however, the discharge remains fetid in odor, experience shows that the danger from the disease is as great, if not greater, than from the operation, while the latter offers at least complete exemption from future danger, if not the certainty of a cure. Hence, under these conditions and in the absence of threatening symptoms, the question whether to operate or not must be decided by the patient himself, or at least by his circumstances. A prompt radical operation is the only safe course in all instances in which irritative symptoms indicate active extension of the disease. This immediate indication is given in all chronic instances of otitic suppuration by persistent dizziness, pain or local tenderness, one-sided headache, or any symptoms suspicious of intracranial involvement.

GENERAL.

Vital Statistics on the Stage.—Ludovic Barnay, the famous Hungarian actor who once delighted New York theatre-goers nearly two decades ago in "Julius Cæsar," says that he has played 3,868 times in 98 cities. He has appeared in 371 pieces and assumed 455 rôles. On the stage he has been married 1,721 times and died 1,120 times. "I was stabbed," he says in his memoirs, "61 times, killed by lightning 51 times, drowned 22 times, poisoned 166 times, beaten to death 86 times, died of heart disease 192 times, assassinated 109 and executed 133 times. Finally I committed suicide 314 and died a natural death 55 times." All of which shows that the pabulum of dramatic material is chiefly composed of murder, lust, violence and other beatific passions. Fancy a drama purged of this element and dealing with angel cake and sermons and you would have the drama of those who wish to deodorize their neighbors and fail to comply with board of health rules in their own back yard.

Gift for Yale Medical School.—The legacies of the late Mrs. Henry Farnam to Yale have been somewhat incorrectly reported. About $52,500 will go to the endowment fund of the Medical School, and about $30,000 to the endowment fund of the university library, the income to be used in the purchase of books. These additions raise the total funds of the Medical School to about $161,000 and of the library to about $360,000. Mrs. Farnam had been a steady and generous giver to various branches of the university, and her gifts enumerated during the last ten years in the treasurer's report amount to more than $20,000.

A Useful Departure.—Henry Phipps, of the United States Steel Corporation, has offered to the Prison Board of the Western Penitentiary a large floral conservatory for the penitentiary, provided the prisoners be permitted to visit the greenhouse. The prison board has accepted the offer. Plans are being made for a large conservatory of concrete, slate, steel and glass to be erected adjoining the prison. The greenhouse will be so arranged that when the

prisoners are not visiting the place it can be thrown open to the public.

The Medical Profession.—In a recent article in the *Medical Library and Historical Journal*, Dr. J. P. Warbasse, of Brooklyn, with other excellent thoughts writes as follows: Hand in hand with the march of civilization have gone the advancements in medicine. To-day the practitioner in medicine lives closest to the lives of the people. No other vocation brings men so close to the home. The clergyman knows people at their best; the lawyer knows them at their worst; the doctor knows them as they are. And yet the doctor is the most misunderstood of men. He strives to inhibit the very conditions from which he gains his livelihood. He conducts societies for the preservation of the public health; he strives for the prevention of diseases; he works to perfect means for shortening the duration of diseases; and, finally, he disseminates his knowledge of these things to all lands. He gives his knowledge to all the world and claims no proprietorship in anything which his colleague may use for the benefit of humanity. He patents nothing. Medical societies have opened their libraries to the public, from which the layman may learn to take care of his health and his family's. The physicians of the world are united into local societies, into national organizations, and finally into international congresses which meet and cooperate for these ends. No reputable physician has any medical information which his brother physician may not have freely for the asking. Are the lawyers of the world banded together to disseminate knowledge for the prevention of litigation? Have the tailors united in an effort to secure greater permanence in styles? Did Sheffield invite Pittsburg to a conference to teach her the secrets of steel? No: these are businesses. The layman is engaged in business and cannot understand these things.

The physician is misunderstood by the lawyer because, on account of these very things, the lawyer looks upon him as a poor business man. The public does not see that philanthropy has any place in business. None but a doctor can judge a doctor. The layman's judgment as to who is the most capable physician is apt to be wrong, for the reason that he measures by standards which we do not recognize. If the layman were wise he would employ a physician to advise him whom to employ to treat him.

As civilization and the mental development of the race have their erratic deviations, so are there kindred erratic exhibitions of medicine. As there are Anarchists and Dowieites, Socialists and Spiritualists, so are there Eddyites and Homeopaths, Osteopaths and Healers. These are not backward steps; they are the products of a higher civilization. The time is not yet when the truth shall reign supreme and alone. There are the lie and the imposition and the bombastic pretense to peck at its heels and pick at the hem of its garment. These come and go. History has witnessed the beginning and the end of thousands of them. They are fungi that have their origin from things of virile life, but they have not the capacity to endure.

While these fads and sects seem to interfere with the progress of medicine, the contrary is really the case. Medicine takes from them the thing that has made them live, and eventually appropriates it to herself. It may be laid down as an axiom that anything which has the power of developing a sect or following must have something good in it. Medicine is an art, because it appropriates the best wherever it can find it and calls it its own. Its mission is to make the human body more enduring and beautiful, to surround it with wholesomeness, to make the senses more perfect and the hand more cunning; and that is a mission which must needs make for the uplifting of the spirit.

Because the physician is engaged in these things, he too is made better. He is uplifted by his own efforts to help others. He shares in the civilizing effect of his own work.

OBITUARY.

Dr. Philip Bissell died from pneumonia last week at the New York Hospital, where he had just completed his interneship. He was born in Rochester, N. Y., twenty-seven years ago and was a son of Willard Bissell, a merchant of that city. He was a graduate of Columbia University, and was a student of marked ability. Dr. Bissel is the fifth or sixth young physician of unusual promise to succumb in the opening year of their career in New York this past year.

Dr. Crawford K. Fritts, the leading physician of Hudson, N. Y., died last week. He had an attack of neuralgia of the heart, and despite heroic methods pursued by his attending physicians, he failed to recover. He was in his fifty-fourth year.

CORRESPONDENCE.

THE TOXICITY OF THE SAPONINS.

To the Editor of the Medical News:

Dear Sir: Out of hand it would be difficult to establish a relationship between hemolysis and the soda water fountain, but in a recent and interesting monograph (Beiträge zur Kenntniss der Saponinsubstanzen, R. Kobert, Verlag Enke, Stuttgart, 1904) this has been very clearly shown.

This monograph embodies the results of the work of Kobert and his pupils on the derivatives of the Saponaria and allied families, which results have been published in the reports of the pharmacological institutes at Dorpat and at Rostock. The work has been in progress since 1883.

Kobert's attention was called to these substances through several remarkable properties. Owing to their toxicity they have been used since the time of Aristotle and perhaps by the Phoenicians to catch fish. Extracts of plants containing these substances when placed in water kill fish with great rapidity.

They have the property in solution of keeping solids and immiscible liquids in suspension for an almost indefinite period, and as such have been used in pharmacy for preparing emulsions.

As their name implies they fulfil the function of a soap. Their solutions have been used in domestic and technical practice for washing fabrics which will not withstand the action of soaps. They also produce a lasting foam similar to that formed by soaps and have been used in beverages to effect the foaming so much desired in soda waters and allied drinks.

Certain members of the family, notably the sarsaparillas have obtained much renown in popular practice as antisyphilitics. Lastly and very importantly, they have a marked hemolytic action and, when introduced into the circulation, are exceedingly toxic to all classes of animals. It is to this last property that Kobert especially calls attention.

The hemolytic action of the different members of the group varies within wide limits. Whereas, the sarasaponin obtained from sarsaparilla induces hemolysis in solutions of 1-125,000, the guaiac saponic acid from

guaiac wood requires a concentration of 1-10 to effect laking of the corpuscles.

Two other important members of the group stand midway. These are *quillaya* sapotoxin which is in common use for foam making purposes and which has a hemolytic action 1-10,000 and *chamælirium* 1-700. This latter is the substance which Kobert provisionally suggests to replace the quillaya bark. By means of chemical reactions which are more or less difficult to effect on a commercial scale it is possible to reduce the hemolytic power of the saponins. Unfortunately this loss in toxicity is accompanied by loss in foaming and the changed saponins are useless for commercial purposes.

The toxic effect of these substances on the organism varies according to the animal used, the manner of introduction, and the specific saponin employed.

A certain relation does exist between the hemolytic power of the saponins and their toxic property, but this relationship is not a simple one. In non-lethal doses the hemolysis occurring in the blood does not always produce a hemoglobinuria. Larger doses do, however, produce a marked hemoglobinuria leading to a fatal issue. The lethal dose of these substances is small in every case. For quillayic acid and sapotoxin the amount is one milligram per kilo, and even less. For fish one part in 300,000 of water is lethal. On the other hand, it is well known that doses of 0.1 to 1.0 gram per os have been taken by individuals with intact gastric and intestinal mucosæ without ill effect.

In suitable cases, however, the ingestion of doses under 0.1 gram gives rise to a highly dangerous condition leading to inflammation and hemorrhage. Kobert is, however, not prepared to say that the hemolysis is the simple cause of death, but believes also that the saponins affect the nervous system.

It is directly in this connection that the work of Kobert is of interest to the clinician. In the treatment of alcoholic inflammations and in inflammatory conditions of the digestive tract it is the custom to allow the use of artificial lemonades and non-alcoholic drinks. It is quite possible under these circumstances to permit the ingestion of as much of the active principle of these foam-creating substances as 0.1 to 1.0 grams per day. It can well be understood that this may cause inflammatory symptoms, the etiology of which may remain dark for some time.

Moreover, in the summer when large quantities of soft drinks are consumed, with at the same time an increased tendency to intestinal inflammation, the use of beverages containing the saponins is doubly contraindicated.

Kobert suggests that in the manufacture of emulsions and non-alcoholic drinks the use of saponins, especially quillaya bark be absolutely prohibited.

As a substitute he proposes either chamælirin, or better, the saponin obtained from guaiac. Other questions such as immunity against these substances, the specific action of cholesterin and the lecithins, which are more of interest to the biologist are taken up.

New York, April 2, 1904.

ANAESTHOL.

To the Editor of The Medical News:

Dear Sir: We beg to state that the use of the name of Dr. Willy Meyer, of New York, upon the label of the new anesthetic "Anaesthol" was introduced without his knowledge, though in entire good faith upon our part.

At his request the label has been changed and, in order to protect the medical profession against unreliable imitations, it will henceforth bear the name of Dr. Weidig, the originator of the new compound.

SPECIAL ARTICLE.

THE MUTUAL RELATIONS BETWEEN TOXIN AND ANTITOXIN.*†

BY PROFESSOR PAUL EHRLICH, M.D., LL.D.,
OF FRANKFORT-A.-M., GERMANY.

INTRODUCTION.

The importance of practical and theoretical study of immunity. Influence of the side-chain theory. Cellular origin of antibodies. Relations between the constitution and distribution of chemical substances and their pharmacological action. Complexity of simple functions.

Opposing views. Criticism of their experimental basis eliminates errors and reverses their significance. Importance of hypothesis to scientific advancement. Heuristic value of theory of immunity. Utility of succinct nomenclature and symbolic representation (algebra, chemistry).

HISTORY OF SIDE-CHAIN THEORY.

Studies upon the localization of various dyes and their relations to cellular chemistry (Methylene-blue, Neutral-red). Production of immunity with poisonous proteids; —independently of Behring (ricin, abrin, robin). Immunity not only bacterial, but a general principle. Quantitative studies on augmenting immunity and determining its degree. Older obscure conceptions of the relations between antitoxin and toxin (union, destruction, cell-protection). Experiments in vitro eliminate obscurities of those on animals. Chemical nature of union demonstrated. Warmth and concentration hasten union.

TOXOIDS.

Difficulty in applying purely chemical conceptions in the case of diphtheria toxin. Law of equivalence apparently violated. Definitions of immune unit; technical toxin-values, lethal dose ("Dosis lethalis"), limit zero ("Limes null"=Lo.), limit death ("Limes Tod"=L†). Different lots of diphtheria toxin though neutralized by a single immune unit contain different numbers of lethal doses. Investigation shows that upon standing the diphtheria toxin loses toxicity, but retains undiminished its affinity for antitoxin. The toxin molecule is quantitatively transformed into non-poisonous toxoid. Chemical illustration (anilin and sulphanilic acid). The simplest explanation of toxoid formation rests upon the assumption that the toxin-complex contains two groups of different functions: (*a*) Haptophores, by which the complex enters into chemical unions; (*b*) Toxophores, which occasion toxic action. Behring's objection, exemplified in hydrocyanic acid, not justified, because of the simple constitution of that poison. Complex organic compounds have repeatedly been shown to contain groups which confer definite properties upon the whole molecule. Anesthesiophore function of the benzoyl group in cocaine; functions of the chromophore and auxochrome groups in dyes; color reactions of proteids due to definite groups (tyrosin, tryptophan, etc.). Evidence of this complex

* Abstract of the first Herter Lecture, delivered before Johns Hopkins Hospital Medical School, April 12, 1904.

† This paper will be published in full in a subsequent issue of the Medical News.

character of toxins also furnished by studies of hemolysins and bacteriolysins, which have their origin in the union of an amboceptor and complement and are analogous to toxins, the amboceptor representing the haptophore and the complement the toxophore group. Kyes' studies on cobra-lecithid.

SIDE-CHAIN THEORY.

Haptophore Group.—The conception of the duplex nature of toxins, etc., forms the basis of the side-chain theory. Views regarding protoplasm. Fundamental nucleus and side-chains (receptors). These receptors subserve normal assimilative processes which are of synthetic character. Only those substances can be chemically incorporated with the protoplasm (assimilated), which possess a grouping most closely related to some constituent of the cell, fitting into its constitution as a key into a lock. The toxins represent, to a certain extent, toxic foodstuffs. It is mere chance whether they encounter suitable receptors in the cells of a particular animal species or not, as is shown by the irregularity in the action of given toxins in the animal kingdom (botulism). Elaboration of the side-chain theory. The antitoxins are receptors, produced in excess, and liberated from the cells. Appearing in the fluids they unite with the toxins for which they have specific affinity and thus protect the cells which have receptors of similar affinity from damage (analogy to lightning-rods). Not only toxins, but also toxoids, call forth antibodies. It is therefore chiefly the haptophore group which causes the cell-reaction, yielding antibodies by occupying the specific receptors. It is doubtful whether this cell reaction is purely regenerative. The great disproportion between the amount of toxin introduced and the quantity of antibodies obtained points to a concomitant cell-stimulation (Bindungsreiz of Wassermann). This is supported by the fact that a single immunization with suitable bacteria (*e.g.*, cholera) or toxin (*e.g.*, that of diphtheria) may induce an abundant production of antibodies.

EVIDENCE IN FAVOR OF THESE THEORETICAL CONCEPTIONS.

1. The demonstration of specific receptors in organs susceptible to a particular poison. Wassermann's experiments: union of tetanotoxin with cerebral tissues. Disproof of opposing views of Behring and Besredka. Locking of native and experimental hemolysins by susceptible erythrocytes.

2. The demonstration by Pfeiffer that during the latent period, before free antibodies appear in the serum, they may be obtained from the bone-marrow with salt solution (loosely bound, partially liberated receptors).

3. Demonstration of the presence of receptors produced and fixed in definitely localized tissues. Increased abrin-locking by the immunized conjunctiva (Römer).

4. Local production of specific precipitins for maja-albumin after intraocular injection (v. Dungern).

5. All attempts to produce antibodies with alkaloids, antipyretics and antiseptics have failed. These substances do not enter into the composition of the protoplasm, they encounter no suitable receptors and therefore fail to call forth a specific antigenetic reaction.

TOXOPHORE GROUP.

The toxophore group need not necessarily be simple but may comprise various constituent groups which may be identical or different. Illustrations from alkaloidal chemistry; strychnine contains two oxygenated radicles both of which produce convulsions and the drug owes its extraordinary toxicity to a combination of the two. Substances of the filicic acid series are active in proportion to the number of filicic butanon groups they contain. Ricin probably contains two toxophore groups, one agglutinating erythrocytes, the other causing its general toxicity. Three varieties of toxoids may be obtained from ricin, one non-toxic but agglutinating, one toxic but not agglutinating; both of these are incomplete toxoids. The third, complete, is neither toxic nor agglutinating (Tarobi). Tetanotoxin and diphtheria toxin also appear to contain various toxophore groups. In the former there may be a lethal toxophore group and a morbific group; and in the case of diphtheria we may have to distinguish between complexes which cause the chronic effects and those occasioning acute manifestations. It is possible that certain partial groups act more powerfully on certain animal species than on others, and this may explain the observations emphasized by Behring that modified toxins meet with a range of susceptibility in the animal kingdom different from that of the original, unmodified toxin. Of practical importance is the question whether for the rapid production of antitoxin it is more advantageous to use only toxoids, or whether the presence of partial components of the toxophore groups exerts a more favorable cell-irritation.

The action of the toxophore groups is generally slow. Since the intravenous injection of toxins is rapidly followed by their locking in the tissues and disappearance from the blood, the incubation-period, which in the case of diphtheria *toxones* may last for weeks, can only be explained by the slow action of the toxophore complexes. This is further exemplified in the hemolysins. Other factors may enter into the production of a period of incubation (studies of Hans Meyer and of Roux on tetanus). It is difficult to express definite views regarding the mode of action of the toxophore groups. Hueppe's hypothesis; experimental evidence wanting.

RECEPTORS. SUSCEPTIBILITY TO TOXINS. RELATIONS TO METABOLISM.

The receptors of the cells are constituents of the protoplasm possessing a certain independent individuality, as is shown by the possibility of causing their augmented reproduction. In respect to the toxins they act as localizers or condensers and may from an infinitely dilute solution occasion a concentration of toxins in particular cells similar to the concentration of picric acid which takes place when wool is immersed in a dilute solution. Susceptibility to toxins may be divided into the following varieties:—

1. Great susceptibility. Toxophilic receptors exclusively in vital organs. Antitoxin production very difficult because of damage to cells, only possible through use of toxoids (guinea pig or mouse and tetanus).

2. Slight susceptibility because of wide distribution of toxophilic receptors in indifferent tissues, *e.g.*, connective tissue, which lock the greater part of the toxins, and thereby protect more important tissues (fowl or rabbit and tetanotoxin).

3. Insusceptibility, though toxophilic receptors be present, because toxophore groups do not act on protoplasm. Abundant production of antibodies. Rare condition (crocodile and tetanotoxin).

4. Insusceptibility through lack of toxophilic receptors. Numerous examples clearly established (crotin, arachnin, specific hemolysins).

Definite receptor-complexes are associated with definite forms of metabolism. Uniform metabolic processes imply uniform receptor-complexes and therefore a uniform susceptibility to toxins (diphtheria toxins and guinea-pigs; tetanotoxin and mice). Individually varying functions reveal themselves in extraordinarily variable susceptibility (*e.g.*, crotin and rabbits). The embryonic erythrocytes of chicks possess no receptors for arachnolysin and are therefore not destroyed by this toxin. Immediately after hatching the development of susceptible erythrocytes begins.

The study of the receptors has been of particular im-

portance in elucidating the processes of assimilation. Former methods applied to damaged cells were not sufficiently refined. Isolated receptors obtained by immunization make an accurate study of assimilation and katabolism more approachable. The reproach brought forward by some controversialists that the theory of receptors should also explain regeneration is extravagant. It is an advance to be able to isolate certain wheels in the complex mechanism of the assimilation-processes and to ascertain their utility. The actual motive power is not revealed and the problem of regeneration of living matter will long remain unsolved.

The demonstration that erythrocytes possess extraordinarily numerous and various receptors is particularly important. It indicates that these corpuscles, in addition to their function as oxygen-carriers, play an important rôle in metabolism in storing intermediary bodies.

Investigation has been greatly aided by a knowledge of the receptors, since they can be used in the analysis of animal and vegetable poisons to separate them into partial-toxins having different haptophore groups. Thus it is possible by specific locking with specific antibodies to analyze snake poison into neurotoxic, endotheliotoxic and two hemotoxic components. Of the latter, one agglutinates, and the other, through the formation of lecithid, hemolyze the blood (Meyer, Flexner, Kyes). Similar analyses of tetanotoxin and diphtheria toxin are possible. The method is a great advance in a most difficult field of research.

CONCLUSION AND PRACTICAL FORECAST.

The immunization industry which has for its aim the production of sera of highest potency has made marked progress. Sera of much higher antitoxic value than have hitherto been obtained will be the result. The knowledge that the immunity reaction is reduced by too highly toxic treatment of the animals is spreading. An effort is being made to restrict this immune reaction to tissues of slight vital importance (connective tissue) and to protect vital organs from injury. In this direction are the methods of immunization with toxin and antitoxin injected separately or after admixture. Thus an apparently neutralized toxin may cause antitoxin production (Park). This is due, as will be explained in the next lecture, to the presense of ultra-toxoids.

Progress in the production of curative sera is to be expected only when it becomes possible to obtain antitoxins of greater avidity than those now procured. That this is theoretically possible is shown by the investigations of Kyes who demonstrated that through the immunization of rabbits with cobra-lecithid it is possible to obtain an antibody of considerably higher avidity than that obtained by Calmette with cobra venom in horses (antivenin). The selection of particularly favorable animal species and the use of toxins of least avidity or ultra-toxones will, most probably, bring this problem much nearer its final solution.

Origin of Fat in Lipemia.—Perhaps the highest amount of fat in the blood on record was found in a case of diabetes by E. NEISSER and L. DERLIN (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6). The blood obtained by venesection was chocolate colored and contained almost 20 per cent.; the urine almost one per cent. and the heart-blood after death 24 per cent. A chemical examination was made of the fat in order to decide its origin; it differed considerably from the fat stored in the organ but closely resembled the fat of the chyle, hence was probably derived from the ingested food.

SOCIETY PROCEEDINGS.

THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

Fourth Annual Meeting, held in New York City, April 1 and 2, 1904.

(Continued from Page 718.)

Influence of Salts on Lytic Serum.—Dr. Ludvig Hektoen, of Chicago, in a paper on the influence of salts on lytic serum, said that normal salt solution has always been used in making the necessary dilutions in experimenting with lysins of various kinds and no objection is raised to its use, but by using the same strength of other salts in solution, some of them might be found to modify the activities of lysins, and Dr. Gustav F. Roediger and himself have shown that chlorides of calcium, barium, strontium, magnesium and the sulphates of magnesium and potassium suspend hemolysis by their action on the complement under certain conditions and that they suspend the bacteriolytic effect of human serum upon typhoid bacilli. Manwaring, he said, has shown that certain salts inhibit the lytic action of goat's serum on dog corpuscles, the amount of the salt necessary varying with the amount of the complement in the serum; and that precipitation of the salts from non-hemolytic serum salt mixtures restores the original hemolytic power which may be destroyed by heat, and concludes that perhaps the antilytic action of the salts is due to the formation of simple salt or ion complement compounds that are hemolytically active. Dr. Hektoen presented tabulated results of further observation of the action of other salts on the lytic substances in a variety of sera. Small quantities of many salts, he said, are capable of inhibiting the lytic action of human serum upon typhoid bacilli and dysentery bacilli. With the exception of $MgSO_4$, alkaline earths are most active in producing this result. He found also that some salts are germicidal when used alone, while a mixture of solutions of them with serum forms a good culture medium for the bacteria. Many salts were used which had no marked effect on bacteriolysis. The addition of these salts to the sera inhibits the bacteriolytic action, but does not destroy that property of the serum. Example: A mixture of $SrCl_2$ and serum is a good culture medium for typhoid bacilli, but if $Na_2C_2O_4$ is added to precipitate the strontium salt, the serum again becomes bactericidal. This is true also of strong solutions of sodium chloride. The same solutions that suspend hemolysis suspend bacteriolysis as a rule, so, he said that there is reason to believe that the complement is the point of attack. Dr. Hektoen does not believe with Behring that the bactericidal action of rats' serum on anthrax bacilli is due to alkalinity, but that it depends upon interaction of amboceptor and complement. Attempts to inhibit bacteriolysis by serum by introducing the salts into animals have proved unsatisfactory as yet, owing to the death of the animals due to the immediate action of the salts. Tables showing the results of large numbers of salts upon the sera of various animals showing antibacteriolytic action were presented. He quoted Kyes as having shown that the hemolytic amboceptor of cobra venom is activated by lecithin, with which the amboceptor may form a crystallizable chemical compound. Cobra venom is also activated by constituents of normal serum, but according to Kyes and Sachs, the complement in guinea-pig serum, which activates cobra venom hemolytically, is different and

distinct from lecithin. Series of tabulated results of experiments by Dr. Hektoen supported these conclusions. Human serum was shown to become antibactericidal by the action of disintegrated typhoid bacilli, and the products of autolysis of typhoid bacilli were shown to have antilytic properties due to the effect upon the complement and soluble products of autolysis of typhoid bacilli to hinder bacteriolysis. These experiments showed, he said, that in typhoid infections not only is the complement used up in the course of the bacteriolysis, but that a certain amount is also neutralized by the soluble products of disintegration of typhoid bacilli. Tabulated results of further experiments showed that decreasing amounts of antilytic solutions give increasing lysis with the same quantity of complement or serum, that increasing quantities of complements give increasing lysis with the same amount of salt solution, and finally, that multiple proportions of the amount of complement and salt in a given mixture maintain about the same lytic value. His experiments show that in certain instances an excess of salt solution above that necessary to prevent hemolysis causes laking of some corpuscles. There is strong probability, he said, of great similarity of nature and structure of various complements in various sera and in the same serum, and there are indications of close relationship in the chemicophysical nature of complements. Dr. Hektoen concluded that in small doses of $\frac{M}{8}$ solutions, many salts prevent lysis in red corpuscles and of bacteria by various sera. The same salts inhibit the activation of cobra venom by guinea-pig serum. The soluble substances of disintegrated typhoid bacilli have antibacteriolytic and antihemolytic properties. The antilytic salts experimented with prevent hemolysis and probably bacteriolysis by virtue of their complements; that probably in their actions complements and antilytic salt solutions follow simple physicochemical laws and are closely related in their chemicophysical properties; that amboceptors appear to be unaffected by antilytic salts in quantities sufficient to neutralize the complements and possibly neutralization of complements may play an important rôle in certain infections.

Concerning the Specificity of the Somatic Cytotoxins.—Dr. Richard M. Pearce, of Albany, said an attempt to demonstrate the relative specificity of the various cystolysins produced in the rabbit, by injecting the various cells and fluids of the dog, sera produced by injection of the liver, pancreas, adrenal and kidney free of blood and serum have a distinct hemagglutinative and hemolytic action. The same is true of the sera of animals receiving normal serum and urine. Animals treated with bile develop a serum which is agglutinative but not hemolytic. The nephrotoxic serum has a distinct action on the kidneys; pancreas, hepatic and adrenal sera have no definite action upon the organs for which such is supposed to be specific. Degenerative lesions of the kidney and occasionally of the liver follows the administration of all the sera. Albuminuria was frequently observed. When the organ with the contained blood is used for purposes of injection, the action of the resulting serum is complicated by the hemolysins present and unless this factor is recognized incorrect conclusions may be drawn. Such sera cause hemoglobinemia, hemoglobinuria with, usually, lesions of the liver or other organs due to agglutinated red blood corpuscle thrombi. It is evident, Dr. Pearce said, therefore, that specificity depends upon the clinical (receptor) constitution of the cells and not upon morphological characteristics —a confusion of the virus of Ehrlich and Morgenroth. Many of the results heretofore deduced as due to cytotoxin specific for the cells of various parenchymatous organs are due, instead, to hemoglutinins or hemolysins.

Parasitic Hemoptysis.—Dr. E. R. LeCount, of Chicago, reported a case which had occurred in the practice of Dr. A. D. Mackenzie, of Portland, Oregon, and demonstrated the ova of the *Distoma Westermanni* which he had found in the sputum of the patient. This, Dr. LeCount said, was the first case of hemoptysis of parasitic origin observed in this country. The patient, a native of Japan, presented symptoms and physical signs, other than his hemorrhage from the lungs, which, for a time resembled those of pneumonia. Repeated examinations had been made also for the tubercle bacilli, with negative results. The ova were first found by Dr. Mackenzie and later by Dr. C. W. Styles, of the Bureau of Animal Industry. Dr. LeCount reviewed previous observations in this country of pulmonary infection with animal parasites in the hog, the cat and the dog. He said that the disease is endemic in Japan and that most of the literature on the subject is in the language of that country, that two forms of disease due to the *Distoma Westermanni* are known to occur, the pulmonary and the cerebral in both of which cysts are found. A single worm has been found, usually, in a cyst in the lung and a bronchiole always leads into a cyst. A mucopurulent or hemorrhagic exudation is usually present. In the cerebral form adult worms and ova have been found in the cysts. Dr. LeCount further said that Taniguchi believed that the walls of the cysts were in part formed by the vessels, when embolism occurred in this disease. Ova have been found also in various other parts of the body and in the intestinal contents. According to Katsurada, the average size of the ova was 93.5μ in length and 57μ in breadth. In Mackenzie's case they were 91.33μ by 55.18μ.

Avian Tuberculosis.—Dr. Veranus A. Moore, of Ithaca, described and illustrated by lantern slides the morbid anatomy and etiology of tuberculosis in fowls. The lesions, he said, are largely found in the liver, spleen, intestines and mesentery, the other organs being rarely found diseased. The tubercle bacilli were found in large numbers in the lesions and pure cultures were obtained. The cultural characteristics were briefly described and Dr. Moore said that the morphology of the organism was found to vary much when grown on different media, being smaller and more uniform in size on blood serum and in Dorset's egg medium longer and containing more granular and involution forms when grown on glycerin bouillon and potato. Fowls inoculated with the pure culture developed generalized tuberculosis, but rabbits and guinea-pigs were not affected by abdominal inoculations. A number of fowls were inoculated with human and bovine tubercle material and others were fed with tuberculous sputum with negative results after four or five months. The difficulty of making a differential diagnosis in living fowls was emphasized. Tuberculin made from human and that made from avian tubercle bacilli had thus far not been successful.

Glioma over the Coccyx.—Dr. F. B. Mallory, of Boston, reported the further history of a case previously presented by him to the meeting of the society in Cleveland, in 1902. The tumor occurred in a woman forty-four years old. It had been noticed

twenty-five years previously, when it was about the size of a hickory-nut. It remained of this size until one year before operation, when it grew rapidly, and reached the size of a baseball. It was not attached to the coccyx and the skin was freely movable over it. A year later metastatic nodules were removed from the right groin. In 1904 she was again operated on and recurrences over the coccyx and in the right groin, and metastases in the left groin were removed. The original tumor, the metastases and the recurrences agreed in gross and microscopic appearances. Each tumor mass consisted of nodules distinctly encapsulated. On section they appeared gray and homogeneous like a sarcoma. There were a few areas of necrosis and of hemorrhage. Under the microscope the structure was that of a carcinoma, namely masses of epitheloid cells embedded in a connective tissue stroma. The peculiarity, however, was that the epitheloid cells in the alveoli had produced a fibrillar intercellular substance which has the chemical reactions of neuroglia fibers. So far as known this is the first case on record of a glioma outside of the central nervous system, or of metastases from a glioma. The type of the neuroglia cells is like that seen in early embryonic life. It is probable that the tumor arose from embryonic remains of the neural canal over the coccyx.

The Blood of Normal Guinea-pigs.—Dr. S. H. Burnett, of Ithaca, said that he had made a careful study of this subject and that in the circulating blood of full-grown, supposedly normal guinea-pigs the red blood corpuscles were found to average 5,276,000 per c.mm. The average percentage of hemoglobin was 94.5. The specific gravity found was 1.053. The average number of leucocytes was 10,897 per c.mm. and that five varieties of leucocytes were found in the peripheral blood, as follows: Lymphocytes cells in which the nucleus occupies nearly all of the cell body of which is strongly basophile and coarsely reticular and was equal in size to the red blood corpuscle or twice its size. The average number per c.mm. is 5.087 or 47.32 per cent. Large mononuclear cells with oval or variously bent and curved nuclei which occupy relatively less of the cell than those of the lymphocyte. The cell body of this variety is faintly basophile and finely reticular. Many of these cells contain one or more vacuales or a rounded body which is often nearly as large as the nucleus. The size of these cells is about twice that of the red blood cell and the average number per c.mm. is 1,090 or 10.05 per cent. Polynuclear cells with polymorphous nuclei, the cell bodies of which contain a moderate number of fine granules which have a weak affinity for acid dyes and are one-half the size of the red cell. Average number per c.mm. 3,257 or 31.52 per cent. Eosinophile cells with polymorphous nuclei usually bilobed the bodies of which contain many coarse circular acidophile granules and are slightly larger than the polynuclear variety. Average number per c.mm. 1,175 or 10.72 per cent. Most cells with polymorphous nuclei and cell bodies containing many strongly basophile granules which are slightly larger than the cosinophile granules. These are slightly larger than the eosinophiles and average 43 per c.mm. or 0.37 per cent.

Varieties of Bacilli Included in the Dysentery Group. Dr. Wm. H. Park, of New York, said that last summer, when this study was undertaken, it had already been shown by Kruse, Hiss, Martin, Lentz, Collins, himself and others that the bacilli obtained from cases of dysentery differed among themselves in their biochemical and agglutinative characteristics. The object of his investigation, he said, was to see whether all the bacilli belonged to a few distinct types or had endless variations. It can be stated that 90 per cent. of all the cases are due to one or the other of these distinct types, and that most of the remaining ten per cent. of bacilli are very closely allied to one of these types. The variety which was met with in the most characteristic epidemics was usually the Shiga type, which does not produce reddening of the peptone mannite litmus media. The second type actively ferments mannite and maltose in peptone mannite media and produces indol. To this type belong the bacillus isolated by Flexner in Manila in 1900, and that from summer diarrhea in Baltimore, by Duval, in 1902. He obtained this bacillus during the past summer from epidemics at Orange, N. J., Riker's Island and New York City. The third type ferments mannite but not in appreciable degree maltose in pepton media. It also produces indol. This type was first isolated by Dr. Park in Dr. Dunham's laboratory at Seal Harbor, Maine, in the summer of 1902. In the fall of that year it was isolated from cases in the Children's Hospital in New York City by Hiss, Wollstein and Collins. During the past summer it was the most frequently isolated type in New York City and in small epidemics north of the city in Mount Vernon, Tuckahoe, etc.

Dr. Park showed the following table giving the reaction of the members of each type to the serum produced through bacilli of the same type and of the other types:

Serum of animal immunized to

Source of Culture	Shiga Type 1-100	Shiga Type 1-1000	Manila Type 1:100	Manila Type 1:1000	Seal Harbor Type 1-100	Seal Harbor Type 1-1000
Type 1.						
Japan (Shiga)	++	++	—	—	—	—
New Haven (Duval)	++	++	—	—	—	—
Mt. Vernon (Collins)	++	++	—	—	—	—
Type 2.						
Manila (Flexner)	—	—	++	++	+	—
Baltimore (Duval)	—	—	++	++	+	—
New York (Goodwin)	—	—	++	++	+	—
Type 3.						
Seal Harbor (Park)	—	—	+	—	++	++
New York (Hiss 7)	—	—	+	—	++	++
Mt. Vernon (Collins)	—	—	+	—	++	++

It was noted that the serum of an animal immunized to a member of either of the mannite fermenting, indol producing types had considerable common agglutinins for the other type; these two types seem to Dr. Park to be in every way nearer to each other than to the Shiga type. This is true, he said, not only in their agglutination affinities but in their having more common immune bodies. The serum from an animal immunized to one of the mannite fermenting types protecting the members of the other type almost as well as those belonging to its own and that this was true to only a slight extent between these types and the Shiga varieties. The cases of summer diarrhea where dysenteric symptoms were absent had as a rule few or no dysentery bacilli. When present they were almost never of the true Shiga type.

Comparison of Living and Dead Tubercle Bacilli in the Production of Antituberculin.—Dr. Trudeau presented briefly the results of inoculation experiments. He showed three photographs of autopsied animals showing the effects produced by inoculation with living bacilli and with dead bacilli, compared with the control animal. These showed a greater diseased condition in the animals injected with dead bacilli and he said that there was a greater death rate among these and that they died in a shorter time. He concluded therefore that there are greater hopes in the injection of living bacilli, in the production of artificial immunity.

Differences in Precipitins Produced by Tubercle Bacilli.—Dr. Edward R. Baldwin, of Saranac Lake, presented the differences obtained in precipitins from two sets of animals immunized with fresh normal saline extracts of tubercle bacilli and the residue respectively. Well marked precipitation was obtained from the extract serum upon both extract and residue. The residue serum, on the contrary, precipitated only the latter. Multiple precipitins or other antibodies with different affinities are possible results, he said, of tuberculous infection.

Observations with Tuberculins from Different Races of Tubercle Bacilli.—Dr. S. B. Wolbach, of Boston, reported upon work undertaken at the suggestion of Prof. H. C. Ernst and which consisted in the treatment of tuberculous guinea-pigs with tuberculin and in making tests for differences in specificity of tuberculins made from human and bovine tubercle bacilli. The cultures used for inoculations and for manufacture of tuberculins were a human and a bovine culture, isolated directly from human and beef blood serum. The work consisted of three parts: (1) The testing of virulences in which the bovine culture was proven more virulent for guinea-pigs and rabbits, though the human culture was a highly virulent one; (2) in testing the strength of the tuberculins the method of Dönitz was used, consisting in the determination of the maximum dose which will cause the death of tuberculous guinea-pigs within twenty-four hours. The tuberculin injections were given at the time when the guinea-pigs begin to lose weight rapidly. By using each tuberculin upon guinea-pigs inoculated with both cultures it was hoped that differences in intensity of its reaction would be found. This proved not to be the case. The tuberculin from the human culture reacted as intensely upon guinea-pigs inoculated with the bovine culture as with the human culture and vice versa. The method of Dönitz was found to be incapable of yielding quantitative results. It was found that the tuberculins made by Dr. Wolbach were approximately equally active and of greater strength than demanded by Koch, that is, that 0.5 gm. should kill a tuberculous guinea-pig of at least four weeks' standing, in from six to thirty-six hours. (3) The treatment of guinea-pigs with skin tuberculosis. Guinea-pigs inoculated with the above culture by the skin-flap method were used. Guinea-pigs inoculated with both cultures were treated with each tuberculin. Treatment was begun at the end of the first week, three injections per week being given, starting with 0.0125 gm. doses and gradually working up to 0.2 gm. doses. No differences in the reaction and effect upon the duration of life were observed between the two tuberculins. The effect of treatment was to prolong life and in a few instances the ulcers healed as described by Koch. This did not occur with the control guinea-pigs. Dr. Wolbach summed up his conclusions reached as a result of the above experiments as follows: (*a*) That there are no specific differences between the tuberculins made from human and bovine tubercle bacilli. (*b*) That the tuberculin treatment is, on the whole, favorable in its action upon tuberculous guinea-pigs. (*c*) As a result of the autopsies upon the guinea-pigs used and upon many others the decision was reached that there are no essential differences in the diseases caused by the two varieties of tubercle bacilli.

The Effect of Certain Blood Sera (Leucocytotoxic) on the Ameboid Motion of Leucocytes.—Dr. Henry Asbury Christian, of Boston, in the Pfeiffer warm chamber studied the action of various blood sera on the ameboid motion of leucocytes. Natural sera, such as that of the rat, rabbit, dog, goose, frog and salamander, had no effect on the leucocytes of these animals, while that of the hen stopped the ameboid motion of the leucocytes of the dog, which was the only example of a natural leucocytotoxin in the blood found. The serum of animals immunized by injections of spleen, liver and kidney are leucocytotoxic, stopping instantly the movement of the leucocytes of the animals whose tissues were used in immunization. This action was produced by the parenchima of the organs injected and not by the included blood, showing that the leucocytotoxic serum can be produced by the injection of cells not of the leucocyte group. The specificity in action of such sera is, said Dr. Christian, similar to that of hemoglobins.

Experimental Production of Liver Necrosis by Hemagglutinins.—Dr. Richard M. Pearce said that the presence of agglutinated red blood corpuscle thrombi in connection with the focal necrosis of the liver of experimental hog cholera had been demonstrated by Boxmeyer and that he himself had produced in the dog somewhat similar necroses by the injection of a hem-agglutinative serum (serum of rabbit injected with dog's corpuscles). This serum in doses 1 c.c. per kilo weight causes in the dog definite focal necrosis in which agglutinative thrombi may be easily demonstrated in the circulating blood a few minutes after the injection of the serum. Other agglutinative sera are that of rabbits receiving injection of dog's bile and may produce similar necroses.

A Simple Method of Isolating from Water, Forms Which Agglutinate with Typhoid Serum.—Dr. J. George Adami described a method devised by Dr. J. A. Chopin and himself. The main objects desired were (1) to employ the maximum amount of the suspected water for culture purposes and (2) to use a large quantity also for purposes of agglutination. The water (*e.g.*, the water from a flowing stream) is collected in sterilized Winchester quarts, holding about two liters. In the laboratory 20 c.cm. of a one per cent. glucose broth is added to each and the Winchesters are then incubated for eighteen to twenty-four hours. Glass tubing of 7 mm. inside diameter is taken in one-half meter lengths, the tubes closed at one end to form elongated test tubes and filed around about one inch from the closed end. Into each of a series of such tubes is placed 10 c.cm. of the incubated water, and now into each is dropped a definite amount of a known typhoid serum. Any form agglutinated by the serum forms a sediment at the end of three to five hours. Then the filed closed end is broken off, the sediment washed with sterilized water, a loopful added to a tube of nutrient broth and from this Hiss, Elsner and neutral red plates are made. The method has brought to light forms which are clumped by high diluting of typhoid serum.

Bacteria in the Mesentery of Normal Animals.—This paper was read for Dr. A. G. Nicholls, of Montreal, by Dr. Adami. The method is easily performed and needs only the magnification given by the one-twelfth immersion lens usually employed, and the presence of bacteria undergoing dissolution can be demonstrated in the rabbit, guinea-pig, cat, etc. It consists of

killing the animal quickly by a blow on the neck, rapid opening of the abdominal cavity under strict aseptic precautions, pulling a loop of the endothelial covering of either side of the mesentery by a sterile swab, cutting out and hardening a small thin piece of the same in formalin, stain preferably by carbol thionin for several hours and careful declorization. If sections of the stomach or intestine be stained similarly it is seen that while at the outer ends of the acini the abundant bacilli stain well and characteristically deeper down they stain only in part and tend to assume diplococcoid forms. Similar diplococcoid forms of degenerating bacteria together with occasional well stained forms are to be seen in the mesentery prepared as above. Most often in the immediate neighborhood of the nuclei of the cells lining delicate lymph and blood capillaries. These may be abundant. Presumably they are carried inwards from the lumen of the intestine by the leucocytes.

Bacillus Agglutinated by High Dilutions of Typhoid Serum; Isolated from Water.—This paper by Dr. O. Klotz, of Montreal, and read by Dr. Adami, described the characters of the form isolated by Drs. Adami and Chopin from water at Montreal which agglutinated with high dilutions of typhoid serum. He compared it with a series of similar forms fermenting various sugar broths and not coagulating milk which had previously been isolated by Carl Sternberg, of Vienna, which also agglutinated with typhoid serum, and called attention to the existence of this group of forms. His, he denominated the *Bacillus perturbans*. It was definitely pathogenic to rabbits and guinea-pigs at first, employing not the strongest sera there seemed to be no difference in agglutinating powers between it and the *Bacillus typhosus*. Later, with stronger sera a human typhoid serum which clumped the typhoid bacillus in dilutions of 1 in 6,200 clumped the *Bacillus perturbans* in dilutions of 1 in 1,550. Similarly a typhoid immune rabbit serum gave complete clumping of the two forms and dilutions of 1 in 4,960 and 1 in 2,480 respectively. Immunizing a rabbit against the *Bacillus perturbans*, its serum agglutinated both the typhoid bacillus and the *Bacillus perturbans* in dilutions of 1 in 2,480. Dr. Klotz said that his observations serve to confirm the conclusions already recorded by other observers that even where a positive result is obtained with relatively high dilutions of typhoid serum it is unwise, not to say mistaken, to regard as specific, the reaction. It is the presence of a typical typhoid reaction plus the clinical symptoms of the case, he said, that must be taken into consideration, and now that typhoid cultures are obtainable in so large a proportion of cases from this blood he suggested that those cultures afford the surest diagnosis. So also in examining suspected water obviously the mere obtaining of agglutination with typhoid serum is not to be regarded as adequate evidence of the existence in it of the typhoid bacillus.

(To be Continued.)

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedics.

Stated Meeting, held March 3, 1904.

The Vice-President, Virgil P. Gibney, M.D., in the Chair.

A Consideration of the Ultimate Results of the Bloodless Replacements of Congenitally Dislocated Hip.—This was the paper of the evening, and was read by Dr. John Ridlon, of Chicago.

Dr. H. Augustus Wilson, of Philadelphia, in the discussion, said that after listening to the very elaborate paper of Dr. Ridlon, he felt as if little remained to be said, except possibly with reference to the cases that Dr. Lorenz had personally operated upon in the Jefferson Medical College Hospital in Philadelphia. When Dr. Lorenz accepted Dr. Wilson's invitation to hold a clinic in Philadelphia, there appeared to be no suitable cases for him to operate upon. A notice was put in the medical journals, and in a few days cases came in large numbers, the great majority not congenital dislocation of the hip, but all sorts and kinds of deformities. Twenty cases of congenitally dislocated hips were selected and submitted to Dr. Lorenz. From these he chose a sufficient number to demonstrate his method of treatment applied to the various ages. The results of the nine cases he operated on in Philadelphia are as follows: Three perfect anatomical and functional results. These patients are under two years of age; one a single dislocation, the other double. Three cases have good functional results. By that it is meant that they are so far improved over their former condition as to make the trivial limp apparent only to an expert. This gives 66⅔ per cent. successes. Six out of the nine have good functional results. One was not reduced—a child aged four years, who had been previously subjected to various forms of tenotomy, stretching in bed, extension, had worn a brace a considerable length of time. In this case there was failure to produce a reduction. Lorenz attempted reduction and failed, after almost exhausting his strength. It was put up in typical position, and in six months radiograph showed the hip to be not reduced. The ultimate result was great improvement of function. A double case, in six months, after the original cast was removed, showed apparent typical replacement. The conditions which made it slip were undoubtedly due to the fact that through a misunderstanding on the part of the physician who had charge of the case (it was not under Dr. Wilson's care), of the necessity for the weight-bearing feature emphasized by Dr. Lorenz. This child was kept at rest, sitting or lying in bed. At no time was it taught any method of extending the legs to get the hamstrings in full extension. It did not step on its foot for six months. The muscles of both legs were atrophied from disuse, the hamstring tendons were contracted so that the knees could not be straightened, and that made the joint slip from a very shallow acetabulum. Dr. Lorenz in June last, saw the case and found it necessary to etherize the child and stretch the hamstrings again. Notwithstanding the second manipulation upon the hamstring tendons, both hips slipped. The speaker had been surprised at the low valuation that Dr. Lorenz placed upon the radiographs in cases of congenital dislocation. Dr. Wilson thought they were useful as a matter of record rather than as a test of conditions. The radiograph of several cases showed a deep acetabulum, completely deceiving those interested as to real conditions present, which were found to be filled with cartilage and fibrous tissue. Casually alluding to the results in the 32 cases under Dr. Wilson's observation in Philadelphia, he said there had been no paralysis of any sort, nor disturbance of the circulation. In one case there was temporary edema of the vulva, necessitating catheterization for forty-eight hours; after that function returned. There is a question as to whether we are justified in considering the classification of perfect, anatomical results. Perfect anatomical results do not always give the best functional results, and function is the object always desired. It is clearly impossible to make a new hip that will be anatomically perfect in cases that have been born with abnormal hips, and the highest ideal should be to obtain functional recovery and a functional result is not always obtained in a so-called anatomical replacement. A boy, eleven years of

age, by radiograph and palpation, showed a full, anatomically perfect replacement, but he had rigid, stiff hips which possibly might become limbered up after a while, but were far from a functional recovery. Too fine a distinction is made in classes of cures. If a standard of functional recovery can be formed, a higher percentage of successful results will be attained, and justice will be done more fully to the man who has taught us.

Dr. Bradford, of Boston, said that the subject of congenital dislocation of the hip had been under such active discussion that it deserved a most thorough, scientific and academic consideration, free from the personal prejudice. The congenital dislocations of the hip at the Children's Hospital have been carefully examined and a report has been made of upward of 130 cases, by the Orthopedic Staff of the hospital. This report has been submitted to an independent committee of surgeons who will publish a statement after a careful examination of the cases, and he did not wish to anticipate the report by an earlier presentation of figures. The anatomical facts of congenital dislocation of the hip were formerly not well understood, but after investigations of the last thirty years, following the valuble pioneer work of Prof. Carnochan, of New York, the pathological anatomy is well understood. The surgical indications made clear by the pathology of the affection used to be met to secure perfect cures. It has been demonstrated in many instances by many surgeons, that perfect anatomical cures have been obtained in Europe and this country, and perfect anatomical cures are what all surgeons aim for and obtain in a certain percentage of cases. How large that percentage of cases is, will be determined by further investigation. In the statistics collected at the Children's Hospital, in Boston, based on observations dating back for twenty years, the results were most encouraging in that it appeared that the percentage of absolute, anatomical cures has been steadily increasing. By cures was not meant functional cures, or transpositions, but results by which the head was replaced in the acetabulum with perfect restoration of gait, shown by measurements, by palpation, by observation and by skiagraph record, and it is probable that in the near future these will be the results that the surgeon will expect to attain It was within the recollection of many surgeons that congenital clubfoot, which is practically a congenital dislocation, was looked upon as a deformity in which a satisfactory functional result was considered all that was to be desired. We have arrived at a stage of surgical skill by which a surgeon, if he does not obtain a perfect cure in clubfoot, is prompted to look for some defect in method. Congenital dislocation of the hip may eventually be looked upon as a distortion of a similar class. Relapses occur after congenital dislocations of the hip have been reduced, in a large number of cases. These relapses have been already considered in a paper presented a short time ago before the New York Academy, so the subject will not be again brought up at this present time, although it is one of much interest and importance, and it is at present not yet determined whether the percentage of relapse is greater after reduction by or without incision, but Dr. Bradford entirely agreed with Dr. Ridlon that in operable cases, the manipulative method as demonstrated by Dr. Lorenz was the method of choice. This may not, however, be considered a permanent solution of the question. Improvements in technic were to be expected in this as in other branches of surgery. At present in congenital dislocation of the hip there is a condition which is anatomically well understood. In certain of the older cases, those with bony change, manual reduction is not practicable. In a large percentage of cases in young children, reductions are not only practicable, but possible, and to be expected. In a certain percentage of these cases relapses occur. Relapse, as we understand after treatment more thoroughly, may be expected to become less frequent. At present manipulative methods are to be tried in all operable cases. Where this fails owing to a folding of the capsule in front of the reduced head, incision is advisable. In cases with osseous change, operations upon the bone are to be considered. It would seem that anatomically there is no greater difficulty in the cure of congenital dislocation of the hip than in the cure of congenital clubfoot, and in the next decade, the gentlemen of this Academy will, no doubt, when meeting together, consider congenital dislocation of the hip one of the readily curable deformities.

Dr. Whitman said that from his own experience he could not accept the reader's statistics as representative. Two years ago he had presented before the Orthopedic Section of the Academy ten patients cured by the Lorenz method, some of whom had been treated five years before. These patients were actually cured in the sense that no evidence of the former disability remained. In his opinion in properly selected cases (the younger the patient the better the prospect of cure) 40 per cent. of the cases should be perfectly cured by this method. He did not, however, limit himself to the Lorenz operation, but having failed by that method he would recommend arthrotomy. By this means one might assure himself that the head of the femur was actually within the acetabulum, or if the femur were so twisted as to make permanent apposition impossible one might restore the normal relation by means of osteotomy. Finally the old Hoffa-Lorenz operation might serve as a last resort to assure the stability which was hardly possible without bony support. It was true that the best result by this method could not compare with the perfect cures attained by bloodless reduction. The average result, however, was better than after transposition. He was inclined to think then that when bloodless surgery had found its limit one should supplement it by other surgery, and that by a more comprehensive treatment the results would be greatly improved. Dr. Whitman said that there were different varieties of transposition which had not been recognized apparently, in the statistics presented. One was caused by hyperextension, in which the head of the femur was forced too far forward so that it could be felt and seen directly beneath the femoral artery. In cases of this character the limb remained, when the plaster bandage was removed, in an attitude of abduction and extension; motion could be restored only by persistent manipulation, and in some cases an anesthetic might be necessary to lessen the distortion. Yet, in this class of cases the final result was likely to be good and even perfect because of the permanency of the reduction. If, on the other hand, the head of the femur were just outside the femoral artery the result was usually unsatisfactory in that the shortening was progressive until the head came to a resting place beside the anterior superior spine. In only one class of cases could such transpositions be regarded as a good result. If, for example, one had transformed a bilateral posterior into a bilateral anterior displacement the contour of the body was improved and the symmetrical disability was markedly decreased, but if in such a case one side were actually cured and the other transposed, the surgeon might be accused of injuring the patient because the swaying gait had been changed to a noticeable limp. In such a case one should always perform the open operation with the aim of assuring stability, even at the expense of a part of the range of normal motion.

Dr. Jacobi asked the earliest age at which a patient

should be operated on when found to have congenital dislocation of the hip. A case might be discovered when a baby was but a few months old; is any operation in order at this time? Usually cases are not discovered at this time but occasionally they are.

Dr. Newton M. Shaffer, in the discussion on Dr. Ridlon's paper, said, while not agreeing with all his conclusions, the paper presents many valuable facts, and however the statistics he presents may be regarded, they form an intelligent basis and a comprehensive one for judging of the Lorenz operation and its results. He regrets his unpreparedness to give a satisfactory analysis of the results obtained in the patients coming under his observation, but preferred to make reference to those only who have been under his care, for a longer or shorter time, at the State Hospital. These were four in number, all operated upon by Dr. Lorenz, either at the Cornell Clinic or at the hospital. The lessons conveyed by a study of these cases—their behavior under treatment—their progress after the gypsum splint was removed—and the results thus far obtained, are most interesting. But at this date, about fifteen months after the operations, it is impossible to state the ultimate results—and it may be years before this can be definitely determined. In all these cases—and all were apparently successfully reduced—the tendency to the condition known as the "anterior transposition" was marked. He thinks that Dr. Ridlon's statement that this is due, in a large measure, to the conditions produced by the tearing of all the resisting tissues, especially the muscles and nerves, is correct. In the after-treatment of this condition one should study the "adaptive muscular conditions" as he has termed it, more closely. Normal muscles shorten and lengthen as opportunity is given, as, for instance, in the acquired talipes equinus associated with the shortened leg in hip disease. In infantile paralysis, the shortening of the unparalyzed muscles is always marked. In lateral curvature, the same thing is observed. Muscles lacerated, as in this operation, for instance, the adductor group, by the force necessary to reduce a congenitally dislocated hip may be so far injured that it may be years before they can regain their normal contractility, if they ever do. Add to this a nerve injury and the condition becomes more complicated. Studying the results which have come under his observation, he should, in the future, give these muscles a much longer time to recuperate, before discarding mechanical protection. In other words, after the plaster-of-Paris splint is removed, a simple steel support should be applied, as for instance, in extensive infantile paralysis, embracing the pelvis with a conventional pelvic band controlling the entire limb to, and involving the foot, with anteroposterior motion, only, at the hip, knee and ankle, with or without perineal pads, as indicated. This would place the femur and the hip under the control of the surgeon and prevent any "anterior reposition" and the "weight-bearing" principle could be scientifically applied, while the patient walks about—with the head of the femur in the acetabulum. Massage, etc., could be used to restore the lost muscular power. He has applied this treatment to two of the patients now under observation at the State Hospital—who are doing well. He regrets he did not apply it to two others who have done badly since they left the hospital, with apparently perfect reposition.

Dr. V. P. Gibney said the presentation of the subject by three or four men who had worked so lately in this line, and especially one gentleman who had come from the city of Chicago with a very well prepared paper and who had given such carefully compiled results, led him to refrain from any discussion. He thought his colleagues would agree with him in saying that the cases operated upon at the Hospital for the Ruptured and Crippled are hardly ready for presentation of final results. In the last Annual Report of the hospital he had given a brief résumé of results, though far from final. With the opportunities afforded at the hospital for protecting the joints and for operative interference, he thought all concerned felt that it is best to reserve statistics until a later date. He believed the results would compare very favorably with those shown by Dr. Ridlon.

Dr. Ridlon said, in answering Dr. Jacobi, that the earliest case of congenital dislocation of the hip he had had anything to do with was one of seventeen months. There can be no question that the earlier one operates, the easier it is to make replacement and the less the injury. On the other hand, the earlier the operation, the more difficult the retention because the delicate baby's skin does not bear covering as does that of an older child. A baby wets the plaster splint. One case operated on by him, which he reported on as having relapsed because the splint was wetted and bent (the child flexed and the head went out backward) was operated on by Lorenz. The result was anterior and supracotyloid displacement. It is an annoyance to have to change a plaster splint, reeking with urine, almost every week for eight months. Earlier than eighteen months, one does not recognize the dislocation; generally not until the child has walked. In one case a child had clubfoot and congenital kyphosis, coming for treatment when six weeks old; it was not known that she had a dislocated hip until she was nearly three years old. From two to four years is the period of choice—when the child is old enough to be cleanly. As to Dr. Whitmans remarks, that the greatest thing to be desired in the treatment of congenital hips would appear to be stability; the speaker would not agree. He had the pleasure of examining cases operated on and cured by Dr. Whitman in 1900. They were certainly replaced and certainly stable, also certainly stiff by the cutting operation. Dr. Ridlon did not consider a stiff hip in a good position, as good for a patient to use or as desirable as a hip with which he can walk, with just a little limp, which can be bent to a sitting position. He thought it best to get a functional result, even if not a perfect anatomical replacement. Dr. Whitman also spoke of different transpositions. Those cases in which the head has lain back of the artery, Dr. Ridlon had called extreme anterior transposition in contradistinction to those lying to the outer side of the artery and on a level with the acetabulum as shown by the X-ray; where the head could be felt but not seen, while those back of the artery can be seen as well as felt by him.

THE BEHAVIOR OF THE COSTAL ARCH IN DISEASES OF THE ABDOMINAL ORGANS AND ITS IMPORTANCE AS A DIAGNOSTIC SYMPTOM.

BY ELLSWORTH ELIOT, JR., M.D.,

OF NEW YORK;

ATTENDING SURGEON, PRESBYTERIAN HOSPITAL, NEW YORK.

THE costal arch, composed of the consecutive portions of the seventh, eighth, ninth, and tenth costal cartilages, extends from the lower extremity of the sternum in front obliquely downward, outward, and backward, parallel to the surface of the body to the apex of the tenth rib behind. It serves as a connecting link between the corresponding ribs and the sternum, thus completing the wall of the lower part of the thoracic cavity. The space intervening between the individual cartilages are composed of the same structures as in an intercostal space, namely, of muscles and of fascial layers attached above and below to the borders of the respective cartilages. To their surfaces, as well as to their connecting ribs, are attached in addition the diaphragm, and, in general, the upper portions of all the muscles of the abdominal wall.

Although, in a strict anatomical sense, the lower border of this arch forms in front and laterally the corresponding most dependent portion of the thoracic cavity (which, posteriorly, decends still further to the level of the twelfth rib), it nevertheless practically forms as well a segment of the upper anterior portion of the abdominal wall, corresponding to that portion of the cavity in which very considerable portions of the liver, spleen, and kidneys, and a moderate segment of the stomach are situated; in fact, the lateral portions of the liver and spleen are in places separated from the costal arch only by a very thin partition of diaphragm, pleural cavity, and lung. The extension upward in this way of the abdominal cavity above the lower level of the costal arch is readily accounted for by the well-marked concavity of the domeshaped diaphragm.

Participating, therefore, in the formation of the walls of both the thoracic and abdominal cavities, and serving as well for the attachment and support of the abdominal muscles, it is not at all surprising that the costal arch should be materially affected by pathological conditions of contiguous organs.

In the normal state, the costal arch participates in the respiratory movements of the chest and abdomen, being slightly elevated during inspiration, and lowered during expiration. This excursion can be prevented during quiet respiration by the gentle pressure of the examiner's hand; in fact, in any part of the respiratory cycle, with the patient in the recumbent position and breathing quietly, the costal arch can, in all its different segments, be forcibly pressed into the abdominal cavity a variable distance, according to the degree of its inherent elasticity. Thus, its sternal extremity—composed entirely of cartilage and supple, as well, in virtue of its intercartilaginous joints, can be depressed a greater distance than its posterior segment, which is more rigid because of the firm ribs with which the cartilages articulate. Again, the arc of excursion gradually diminishes as the patient grows older, due to calciferous degeneration and the resulting solidification of the costal cartilages and the not infrequent obliteration of their joints. In the healthy adult, the completion of ossification in the contiguous ribs account for the fact that the movement of the costal arch is not as extensive as it is in children, although it is very much more extensive than in elderly people.

This normal excursion of movement of the costal arch is frequently disturbed, and this is true not only of its active respiratory movement, but more especially of that passive movement toward the abdominal cavity which it may be made to describe through the pressure of the examiner's finger. Interference with its active respiratory movement is elicited by inspection and is manifested chiefly in asymmetry of expiration, the less extensive expiratory recoil of the affected side being checked in a purely mechanical way, before it has been fully completed, by the presence of underlying neoplastic or inflammatory matter. In these cases the pathological condition must be painless, or, at all events, the pain, if present, must not be intensified by respiration for in painful conditions the resulting involuntary inhibition of respiratory movement affects both arches alike, irrespective of the side in which the inflammatory focus is situated, and no criterion of comparison exists. Hence asymmetry of the elastic recoil of the costal arch is to be observed chiefly in contiguous neoplasms and cysts, and in inflammatory conditions only after the subsidence of the acute and subacute stages and their associated pain and tenderness has taken place. Under these circumstances, accumulation of pus, as in "cold" abscess, may interfere with the recoil of the overlying arch.

Any change in the passive movement of the arch can be detected naturally only by palpation, and in eliciting this symptom, not only should the nature or character of its resistance to the surgeon's finger be determined, but one should observe as well whether the resistance is participated in equally by the entire arch or is most marked in one of its segments. In both normal

and pathological conditions the degree of what may be called the "costal resistance" can be roughly estimated by the distance which the costal arch may be made to traverse through the moderate pressure of the examiner's fingers. The examination should always be conducted with the patient in the dorsal position, and the abdominal muscles should be relaxed as far as possible by flexion of the thighs and by directing the patient to breathe quietly, with the mouth slightly open. The degree of costal resistance is then best ascertained by placing the extremities of the second, third, and forth fingers of either hand, respectively, on corresponding segments of the costal arches. Quick but gentle pressure is then made simultaneously, during expiration, in a direction toward the vertebral column, and any difference in the degree of mobility of either arch carefully noted. Proceeding downward and backward from the sternum to the tenth rib along the lower border of the costal arch, successive segments are then compared with each other and the presence of costal resistance in any segment readily determined. In case of bilateral costal resistance, symmetrically developed, pressure exerted simultaneously on the costal arches would decrease the distance between to a very much less extent than in normal.

By a similar procedure, the relative resistance of the diferent segments of one arch may be ascertained, and by unusual deviation from the normal condition detected without comparing the affected segment with the corresponding segment of the opposite side. In this connection, however, the greater normal elasticity of the sternal extremity must not be forgotten, and the desirability of supplementing the examination by a comparison of the abnormal with the normal side cannot be too greatly emphasized.

Under normal conditions, either costal arch may be depressed in this manner a very appreciable distance, and it may roughly be stated that in children, especially near the sternal extremity, this distance is somewhat greater than an inch; in adults, and as the vertebral extremity is approached, between one-half and three-quarters of an inch, while in old people, the distance decreases considerably less than one-half an inch. On the other hand, in pathological conditions, both the character and degree of costal resistance vary very widely. Thus the resistance is of a hard, unyielding nature in the presence of underlying neoplasms, the sensation here imparted not differing materially from the sensation imparted by the palpation of a similar immovable growth on the exterior of the body; in a general way, it may be described as "board-like" in quality, and is not in any sense of the word elastic. In the presence of an acute or subacute inflammatory process, however, the costal resistance is very highly elastic, and the excursion of its movement very considerably limited. In the early stages of such a condition, before the formation of exudate, the increased resistance presented is due to more or less complete immobilization of the costal arch through the reflex contraction of its attached muscles. Subsequent exudation of serum or pus still further increases the pre-existing costal rigidity, and diminution is observed only after subsidence of the acute stage has taken place.

It is very important to emphasize, that asymmetry of costal resistance may be detected when there is no marked difference in the respiratory movement of the costal arches. Thus, as has previously been mentioned, in all acute inflammatory conditions of adjacent organs, the involuntary inhibition of the respiratory movement of the costal arch affects both sides alike. The difference in the costal resistance in a case of this character is, however, easily appreciated, and only in those instances (which must be very rare), in which the pathological process is symmetrically developed in the upper half of the abdominal cavity could any difficulty in eliciting this symptom be encountered.

Increase in costal resistance may or may not be associated with tenderness or pressure. Resistance due to the presence of neoplasm may usually be detected without pain or discomfort to the patient. On the other hand, pressure on the affected segment of the costal arch in adjacent inflammatory conditions almost invariably elicits tenderness if the process be acute, and occasionally in chronic cases as well.

The behavior of the costal arch in the presence of painful inflammatory conditions in the lower half of the abdominal cavity sometimes deviates from the normal. In these cases, respiration is involuntarily largely thoracic, and the abdominal muscles are held motionless in order that there may be the least possible displacement of the inflamed organ. This accordingly results in a symmetrical decrease of the costal respiratory movement, and, on palpation, a corresponding symmetrical increase of the costal resistance may be observed, although it is usually not well pronounced. Notwithstanding, however, that inflammatory processes in the lower half of the abdominal cavity are not generally associated, in their early stages, with any appreciable change in the degree of costal resistance, subsequent extension upward, should it occur in any instance, will result in the gradual development of this resistance as soon as the inflammatory process approaches a costal arch. In these cases the manifestation of this symptom serves a most useful purpose, not only as an indication for immediate operative interference, but also as a guide to that part of the abdominal cavity in which the inflammatory process is most rapidly extending, and to which the surgeon's efforts should be energetically directed.

Case I.—P. J. H.; male, aged thirty-three years; admitted to the Presbyterian Hospital March 27, 1902. Patient denies venereal trouble. Has always indulged moderately in alcoholics. Fourteen years ago suffered from an attack of acute intermittent fever. During the past six

years, patient has had occasional attacks of indigestion. On January 27 last, patient developed for the first time an attack of severe, cramp-like pain, located in the right hypochondrium, lasting between eight and nine hours, and associated with chilly sensations with subsequent fever. The subsidence of the pain was followed by jaundice, the stools became clay-colored, and the patient was in bed for four days, during which time there was tenderness and swelling over the region of the gall-bladder. The jaundice and clay-colored stools persisted for from between two and three weeks, and then disappeared, the patient feeling perfectly well and able to resume work. On February 24 there was a similar attack, the acute, cramp-like pain lasting for seventeen hours, and again on March 25, when the pain persisted for twenty-four hours.

Examination on Admission.—There is tenderness over the right hypochondriac region and a small mass can be felt, movable with respiration, having the configuration of the gall-bladder. There is considerable rigidity of the upper portion of the right costal arch and of the upper part of the rectus directly beneath it. There is slight icterus, with moderate pulse and temperature elevation. At the end of several days, the local symptoms of inflammation together with the icterus, had subsided, and both pulse and temperature had returned to normal.

Operation. (Gas and Ether).—Vertical incision along the outer border of right rectus about four inches in length, and deepened to and through the peritoneum. The gall-bladder was embedded in a mass of omentum, the upper border of the transverse colon being adherent to the anterior border of the liver. After separation of the adhesions, the gall-bladder was exposed and was found to be slightly increased in size with a very much thickened wall. The neck of the bladder and the cystic duct were then enucleated from the bed of adhesions in which they were contained, and through their wall numerous calculi could be felt. The gall-bladder was so firmly adherent to the under surface of the liver that its separation could not be accomplished without risk of hemorrhage. It was therefore opened, some forty calculi of varying size removed from its interior, and after the excision of its mucous membrane, it was sutured to the parietal peritoneum, as in a typical cholecystotomy. Drainage.

Postoperative.—There was moderate temperature and pain. After a week or ten days the bile found its way down the common duct, and the clay-colored stools disappeared. On May 22, the date of discharge, a small superficial sinus persisted, which subsequently closed.

Subsequent History.—Patient continued well for about fourteen months. At the end of that time, some soreness and redness developed in the cicatrix, and on examination a small elastic mass could be palpated. Under an anesthetic the swelling was incised and a small abscess evacuated. Through the abscess cavity the finger could be inserted into the gall-bladder, the walls of which presented a smooth, velvety surface. Only at its fundus, where it emerged into the abscess cavity, was there any evidence of cicatricial tissue. The abscess cavity was drained and quickly closed by granulation without the establishment of a biliary fistula. Since that time (six months ago) there has been no further trouble.

Case II.—R. M., female, aged forty-four years; admitted to the Presbyterian Hospital December 22, 1902. With the exception of occasional attacks of subacute rheumatism, patient has always been well until the development of the present trouble. Last July, after a hard day's work, patient was seized with a severe pain, extending from the pit of the stomach up to the right breast, lasting about one and a half hours and followed by fever and perspiration. During the following night and the next day there were several attacks of slight hematemesis. There was also a slight tinge of jaundice, lasting only for several days. Five weeks ago the second attack occurred, similar in its general features to the first, but more severe. Ever since then, these attacks have been repeated on alternate days, without hematemesis, and three weeks ago pain in the right shoulder-blade developed. During this time patient has been unable to attend to her household duties.

Examination on Admission.—There is tenderness on pressure over the region of the gall-bladder, with moderate rigidity of the corresponding portion of the costal arch and of the upper portion of the rectus muscle. No mass can be felt. There is moderate jaundice. Temperature, 100° F.; pulse, 100; both becoming normal on the day after admission. On the third day after admission, temperature rose suddenly to 105° F., the pulse to 100. On the fourth day, the temperature was normal in the morning, but rose to 104° F. in the afternoon. On the fifth day, the temperature rose to 103° F. and then gradually fell, becoming normal at the end of the week. During this time, there was moderate leucocytosis, but repeated examinations of the blood failed to detect the presence of any variety of plasmodium. The local symptoms of tenderness and rigidity had persisted practically unchanged.

Operation January 9 (Gas and Ether).—Vertical incision along the outer border of the right rectus. On opening the peritoneal cavity, the duodenum was found adherent to the under surface of the liver in what corresponded to the fissure of the gall-bladder. The gall-bladder itself was shriveled up to a small mass of connective tissue containing calculous material. It was separated from the tissue in which it was embedded and removed after ligation of the cystic duct. Closure of the abdominal wound in layers after the insertion of a small cigarette drain to the stump of the divided duct.

Postoperative.—Nausea and vomiting per-

sisted for several days, during which time the pulse varied from 120 to 136 and the temperature between 100° and 102° F. At the end of the third day the bowels moved to catharsis, and a biliary fistula became established. Subsequent convalescence, interrupted only by an accumulation of discharge in the wound, three weeks after the operation. Patient has been perfectly well during the past year.

Case III.—C. H. W., female, aged forty-four years; admitted to the Presbyterian Hospital February 8, 1903. Family and personal history negative. Patient has had three attacks of biliary colic, one three years ago, one two years ago, and the last ten days ago. These have all been characterized by dull abdominal pain, most intense in the lower right quadrant, radiating to the epigastrium and up the back, lasting from four to six hours and necessitating the patient's going to bed. There has been occasional vomiting during the attacks and considerable constipation. There has never been any jaundice. Three days ago, the fourth and most severe attack developed, the character and the location of the pain being the same as in the previous attacks.

Examination on Admission.—There is rigidity of the upper portion of the right costal arch and of the adjacent rectus muscle. A smooth, elastic mass of oval shape may be felt occupying the region of the gall-bladder, extending down from the lower border of the liver to a point one inch below the umbilicus. It is tense and elastic, and by bimanual examination fluctuation may be detected. It is dull on percussion. The patient was treated by local applications of ice and kept in bed. At the end of ten days the pain had disappeared, the mass had greatly diminished in size, reaching inferiorly to a point two inches above the level of the umbilicus. Some costal rigidity still persisted. During this interval the temperature reached a point no higher than 100° F. and the pulse at no time exceeded 90.

Operation, February 20, (Gas and Ether).—Vertical incision along the outer border of the right rectus. On opening the peritoneum, the omentum was found adherent to the gall-bladder, which was greatly thickened, somewhat distended, and contained a considerable amount of thick fluid, detritus, and hardened concretions. After the separation of the omentum, and the examination of the cystic and common ducts, which were found to contain no calculi, the gall-bladder was opened and a cholecystotomy performed, the mucous membrane having been removed with scissors and forceps. A probe could be passed through the gall-bladder into the duodenum. The convalescence was uninterrupted, the resulting biliary fistula closing in about six weeks. There has been no recurrence.

Case IV.—M. W., female, aged forty-two years; admitted to the Presbyterian Hospital April 6, 1903. Family and personal history negative. Fourteen years ago patient was seized with abdominal pain, cramp-like in character, located in the epigastric region on either side of the median line, but more severe on the left side, lasting for several days. Since that time these attacks, preceded by a chill and frequently accompanied by nausea and vomiting, have recurred at intervals of every month or two until the last six months, when the attacks have occurred as frequently as every week or ten days. Each attack lasts generally about one or two hours, occasionally for as long a time as two days. Seven years ago, during an attack, jaundice developed and has recurred frequently during the past six months. The attacks have also been characterized by pain in the back.

Examination on Admission.—There is tenderness in the region of the gall-bladder, but no mass can be felt. There is rigidity of the corresponding portion of the costal arch and of the adjacent rectus muscle. On the day of admission, the temperature rose to 106° F., preceded by a chill, the pulse to 120. On the following day both the pulse and temperature were normal.

Operation (Gas and Ether).—Vertical incision along the outer border of the right rectus. On opening the abdominal cavity, the gall-bladder was completely buried in a mass of adhesions of omentum and duodenum. These were readily separated, however, and the bladder was dissected from the under surface of the liver to a point corresponding to the junction of the cystic and hepatic ducts without any considerable hemorrhage. The common duct was found to be free, a probe being passed down into the duodenum. The pancreas was thickened, and the foramen of Winslow was obliterated. The cystic duct was ligated with chromic gut and the abdominal wound closed after a cigarette drain had been inserted down to the stump of the divided duct.

Postoperative.—The patient suffered but little pain. After the end of a week the drain was removed. At no time was there leakage of bile. At no time was either the pulse or temperature above 100. Examination of the gall-bladder showed its wall to be very much thickened and its cavity to contain several hundred calculi about the size of dice. Its wall was considerably inflamed. Patient has enjoyed excellent health since the operation.

Case V.—M. C., female, aged sixty-six years; admitted to the hospital March 16, 1902. Two years ago patient suffered from colicky pain in the region of the gall-bladder, radiating to the opposite side and regularly followed by chills, fever, constipation, and jaundice. These attacks recurred at intervals of four months, and recently as frequently as two or three times a week. The duration of the attack has varied between one and two days. Patient has lost twenty pounds in weight and has become very weak.

Examination on Admission.—Patient is moderately jaundiced. On palpation, there is increased costal rigidity in the region of the gall-bladder and of the adjacent rectus muscle. By bimanual examination the smooth oval outline of

the gall-bladder may be felt projecting a distance of two inches below the lower level of the liver. It moves with respiration. Examination of the urine shows it to be of a specific gravity of 10.20, to contain a small amount of albumin and hyaline casts. The patient's discomfort was so great and the progressive loss of flesh and strength so marked, that she desired to take the risk of an operation notwithstanding the unfavorable condition of the urine.

Operation (Gas and Ether).—The gall-bladder was exposed through a vertical incision along the outer border of the right rectus, and was found to be moderately distended and free from adhesions. Owing to her general condition, a cholecystectomy was considered ill-advised, and therefore after noting the absence of any calculi in either the cystic or common ducts, the gall-bladder was incised, its contents evacuated, and a cholecystotomy performed. The gall-bladder contained a considerable amount of thick mucus and several friable calculi of large size.

Postoperative.—The patient did nicely for forty-eight hours, the pulse remaining under 100, and without special rise in the temperature. At the end of that time the urine decreased rapidly in quantity, the albumin and casts increased, and the symptoms of uremia became established, the patient dying one week after the operation. Unfortunately no autopsy could be obtained. There was no symptom of peritonitis.

Case VI.—L. J., aged twenty-five years; admitted to the Presbyterian Hospital November 10. Patient was always well until about two years ago. At that time, and again six months later, patient suffered from two attacks of catarrhal appendicitis, of which the latter was the more severe. Shortly after the subsidence of the last-mentioned attack, the appendix was removed, the wound healing by primary union. The patient continued to enjoy excellent health until one year ago, when, without warning, a severe colicky paroxysmal pain developed in the right hypochondrium radiating from there to the epigastric region and back. Icterus developed, the stools became clay colored, and the patient was confined to bed for three weeks, chiefly on account of the severity of the paroxysmal pain. The attack then subsided and the patient was well until five weeks ago, when the pain recurred. On this occasion it was continuous, and rapidly became so severe as to require hypodermics of large amounts of morphine. This attack has been associated with moderate jaundice. There has been scarcely any rise of temperature at any time during the attack.

Examination on Admission.—There is acute tenderness on pressure in the region of the gall-bladder, with rigidity of the upper segment of the rectus. The adjacent portion of the costal arch is very rigid and cannot be depressed any appreciable distance toward the vertebral column. On bimanual examination a small rounded mass about the size of a lemon can be felt projecting downward below the free border of the liver at a point opposite the junction of the eighth and ninth costal cartilages. For the twenty-four hours preceding operation, the temperature varied between 99° and 100° F.; the pulse remained between 70 and 80. There was 15,000 and 20,000 leucocytosis respectively in two examinations, separated by an interval of twenty-four hours.

Operation (Gas and Ether).—A vertical incision along the outer margin of the right rectus to the upper extremity of which was later added a horizontal incision extending inward through the fibers of the rectus. The gall-bladder was completely hidden from sight by the adherent great omentum and colon, but was rather easily enucleated down to the region of the foramen of Winslow. The gall-bladder was of large size, its walls thickened and greatly distended, and its separation from the liver above was accomplished only with considerable difficulty. No calculi could be felt in any part of the common duct, and the organ was removed by the division of the cystic duct between clamps, the divided duct and its accompanying vessels being subsequently ligated with chromic gut. After the insertion of a rubber drain down to the stump, and a cigarette drain to the same place through a counter-opening in the right flank, the abdominal wound was closed. Examination of the gall-bladder showed its wall to be very considerably thickened, especially in the vicinity of the junction of its neck and the cystic duct, where almost complete obliteration has resulted from the previous productive inflammation. Its cavity contained a considerable quantity of thick turbid fluid containing a small quantity of bile only. There were two large faceted calculi of the size of acorns and of a peculiar nutmeg appearance.

Postoperative.—During the first twenty-four hours there was a gradual increase in the pulse and temperature from 88 and 101° F. to 128 and 104° F. respectively in the afternoon. There was considerable pain and some nausea and vomiting. There was a free discharge of bile from the upper wound on the second day, and forty-eight hours after the operation the pulse had diminished to 94 and the temperature had receded to 103° F. On the third day the bowels moved to catharsis, the stools being clay-colored. From this time there was a gradual subsidence in the temperature, and the pulse varied between 72 and 80. Some distressing hiccough, however, continued until the beginning of the second week. At about the end of the second week the biliary discharge decreased and the stools began to lose their clay color. At the end of the third week the amount of biliary discharge was very slight. At no time was there any discharge of bile through the counter-opening in the flank, which promptly closed after the removal of the drain. Five weeks after the operation, patient returned to work with a very small biliary fistula.

Case VII.—Acute Cholecystitis without Calcu-

lus.—F. K., male, aged thirty-seven years; admitted to the Presbyterian Hospital January 31, 1902. Patient, a painter by occupation, admits a moderate beer-habit, until ten years ago, since which date he has drunk but very little.

For the past fourteen years, at some time during the summer, patient has had an attack of diarrhea with slight jaundice, lasting for two or three days. The last attack, one year ago, was more severe than any of the others. The present attack began one week ago, with a chill, followed by a rise of temperature to 105° F. There was vomiting and pain over the vicinity of the gall-bladder. The bowels were constipated and lighter color than normal. The urine was high-colored.

Examination on Admission.—The whole abdomen was slightly retracted. There is pain and tenderness over the gall-bladder, but no enlargement can be detected. There is rigidity of the corresponding part of the costal arch and of the adjacent rectus. There is also moderate rigidity of the lower right quadrant and of the entire left half of the abdominal wall. Temperature was 103° F., the pulse 100 (at no time higher), both rapidly decreasing and reaching normal within several days, with simultaneous subsidence of the local symptoms.

Operation One Week after Admission (Gas and Ether).—A vertical incision over the outer upper border of the right rectus deepened into the peritoneal cavity. The gall-bladder was distended, its wall was thickened, and it contained turbid bile. Its lining membrane was congested. There were no calculi. A probe could not be passed into the duodenum. The operation was completed by suturing the gall-bladder to the parietal peritoneum and inserting a drain of gauze into its cavity.

Postoperative.—The convalescence was uneventful, the biliary fistula closing within two months. December 1, 1902. Patient has enjoyed excellent health since the operation.

Case VIII.—Cholelithiasis in the Quiescent Stage.—N. P., aged thirty-one years; admitted to the Presbyterian Hospital May 31, 1902. Patient was always well until five weeks ago, when, without known cause, she was seized with an attack of vomiting and of general abdominal pain, becoming localized within twenty-four hours over the region of the gall-bladder. Subsequently the pain extended to the right scapular region. There was slight jaundice and fever. The stools were of a greenish color and constipated. The pain was so sever as to require chloroform inhalations. In forty-eight hours the attack had subsided. One week later, a similar attack occurred, lasting for thirty-six hours, and followed by pain in the right scapular region for days afterward.

Examination on Admission.—There is pain and tenderness over the region of the gall-bladder, the pain being also elicited by indirect pressure through the overlying eighth costal cartilage. There is rigidity of the corresponding portion of the costal arch, but none of the adjacent rectus muscle. In other respects abdominal examination is negative.

Operation (Gas and Ether).—A vertical incision was made along the outer border of the right rectus. On opening the peritoneum, the gall-bladder presented, free from adhesions, of small size, firmly fixed to the under surface of the liver, and through its walls several calculi could be felt. The foramen of Winslow was obliterated, but no calculus could be felt in either the cystic or common duct. The gall-bladder was cautiously opened and six calculi, each faceted and about the size of an acorn, were removed. The mucous membrane was excised, and the bladder stitched to the parietal peritoneum. No probe could be passed into the duodenum.

Postoperative.—Patient had several attacks of sharp abdominal pain, resembling biliary colic, during the first six hours after the operation. These attacks ceased with the generous discharge of yellow-colored bile through the fistula, and the further convalescence was undisturbed and uneventful, the biliary fistula closing completely within six weeks. December 15, 1903. Patient has enjoyed excellent health since the operation.

(To be Continued.)

THE PULSE AS A GUIDE TO THE LIFE INSURANCE EXAMINER.*

BY ROBERT H. BABCOCK, M.D.,
OF CHICAGO.

Life insurance companies justly attach great importance to the records of the pulse, especially as regards its rate and rhythm, but so far as I am aware most of them do not lay particular stress upon its tension. So many and diverse conditions influence pulse rate and rhythm that, considered by themselves, these characteristics are of minor importance, and therefore in the apparently healthy man they should be considered in connection with the blood pressure. For this reason it is proposed in this paper to discuss all three characteristics of the pulse with relation to their bearing on life insurance examinations.

Since a persistent pulse rate of more than 85 is by most companies considered a barrier to insurance, it will be well to first discuss the value and causes of abnormal frequency of heart-action. In the first place clinical experience teaches that a pulse rate of even 100 may be natural to some individuals, and so great an authority as Gibson has stated that more importance is generally attached to undue acceleration than this feature of the pulse deserves. Persons to whom such unusual pulse frequency is habitual are generally of a neurotic temperament, which probably accounts for their tachycardia, and Gibson cites the instance of an Edinburgh shopkeeper who, in addition to a pulse rate never

* Read before the Society of Life Insurance Examiners, December 22, 1903.

below 100, manifested pronounced agoraphobia. This fact should therefore be borne in mind when estimating the significance of persistent rapidity of the pulse.

In the great majority of cases tachycardia is not natural to the individual, but depends upon some factor which puts vagus control in abeyance, or counteracts its influence through stimulation of the accelerator nerves of the heart. Among such exciting factors tea, coffee and tobacco, when used to excess, stand forth conspicuously. Tobacco also slows the action of the heart (Gibson), but it has been my observation that it more often accelerates the pulse, even to the extent of occasioning palpitation. Its effect is said to sometimes persist for six months, or even more, after its abandonment. In this country I believe coffee has to be reckoned with more often than tea, and I can recall several instances of tachycardia and palpitation, in which there was a history and admission of immoderate consumption of this beverage. In one healthy young man tachycardia and frequent intermittence were by himself attributed to coffee and cigars. Alcohol is another recognized cause of frequent heart-action which should always be borne in mind. Not only does it accelerate the pulse for the time being, but old topers often display persistent increase of the pulse rate, and in them, of course, one is naturally suspicious that a chronic myocarditis is at the bottom of the tachycardia.

The caution that should be exercised in attributing serious import to mere frequency of the pulse is exemplified by the instance of a man forty-nine years old, whom I saw recently. He had a pulse rate of 120, yet was without subjective consciousness of the fact. There was nothing to point to heart disease and inquiry elicited the statement that two hours previously he had submitted to an intranasal operation that had necessitated the application of cocaine.

The most frequent, and to my mind the most annoying, cause of tachycardia is the psychical disturbance attending examination of the heart. In some instances the individuals are outwardly composed and assert their indifference to the examination, yet their hearts race away as if possessed. The examiner feels confident of the nervous influence at work and yet he knows that to record a pulse rate of 110, or perhaps 120, will be very apt to invalidate the man's prospect for insurance.

Furthermore, under the influence of excessive frequency of contractions, changes take place in the cardiac findings which become puzzling or are unsatisfactory to record. The apex beat becomes feeble and ill-defined, the first sound at the apex is murmurish, or perchance actually replaced by a faint murmur due perhaps to temporary lack of perfect tightening of the valve-segments by the pull of the papillary muscles. Under such conditions the area of relative dulness may be actually increased transversely, as I have many times observed. What is one to do in these annoying and puzzling cases?

So far as possible the physician must take cognizance of other signs of nervousness, as flushing of the face, coldness of the extremities, slight tremor, etc., and he must resort to devices calculated to divert the patient's attention. Thus it has seemed to me advisable to study the pulse while at the same time plying the person with questions concerning his past history or engaging him in conversation on some topic foreign to the matter in hand. Any practitioner of experience may thus gain a fairly accurate knowledge of the pulse rate, even if he does not actually count the pulse at the time. Later on the record can be made without attracting particular notice, or the count may be compared with one made at the close of the chest examination after some reassuring words have been spoken.

I have sometimes found it useful to stand behind the patient and count the carotid beats while he is engaged in the recital of his anamnesis. It is also a good practice to make those nervous individuals recline at ease on a couch when the excited heart will often quiet down materially. After a time they may be told to jump up suddenly, or to hop on one foot about the room for the purpose of testing the competence of the heart, for it has been my observation that a merely excited heart does not show as marked contrast between the rate of the pulse at rest and during exercise as is the case when the tachycardia is due to cardiac inadequacy.

An important matter in determining the significance to be attached to undue frequency of the pulse is its tension. Only exceptionally is blood pressure materially increased by pronounced tachycardia, such as is apt to attend psychical disturbance, whereas increased frequency of the pulse due to some pathological disorder of myocardium is generally associated with increased pulse tension. The statement is generally made that a slow pulse is also a tense one, or conversely that a tense pulse is also slow, but my experience leads me to agree with Rosenbach in his assertion that increase of tension and acceleration are generally combined. Of course, this statement must not be understood as applying to increased frequency of the pulse due to valvular disease, but to that form of hypertrophy seen in the chronic myocarditis of robust middle-aged men with such capacious chests that accurate determination of deep-seated cardiac dulness is difficult. In such a person, therefore, with a pulse rate of 85 to 90 the physician should carefully study the degree of arterial tension.

There are several other causes of abnormal pulse frequency which should be borne in mind. It may be a symptom of pyrexia, and hence it is wise to take the temperature when accelerated cardiac action is observed. It is also most important to remember that tachycardia is said to be a symptom of heart syphilis, especially if combined with irregularity and not attributable to any other ascertainable cause. One should not forget also that abnormal frequency of heart action may be a symptom of the irritable heart of the young

man, which is overstrained by athletics or is weakened by masturbation or venereal excess. Such cases are by no means uncommon. Finally in all cases minute inquiry should be made concerning some recent illness, such as typhoid fever, diphtheria and influenza, since it is well known that the heart my remain rapid for weeks or even months after convalescence, even without obvious signs of cardiac disease.

In concluding this portion of my paper I think it may be safely stated that a pulse rate of over 85, or even of 100, is not to be regarded as in itself indicating cardiac disease. In persons past middle age it is possibly of more serious import than in the young, but even in the former it is not to be regarded as of pathological significance, if no signs or symptoms of beginning inadequacy can be discovered. If, on the contrary, it is associated with abnormally high and sustained pulse tension in a man of middle age with a corpulent abdomen, tachycardia is to be regarded as an early sign of heart-strain and consequently of weighty import. I would not consider such an individual a good risk.

Lowering of the pulse rate to below 60, which is, I believe, the minimum number of heart beats per minute allowed by insurance companies, requires but brief discussion. It likewise may be normal to the individual, yet, even when not congenital, it is not always to be looked upon as denoting some cardiopathy. Nevertheless, unlike tachycardia, it is not the result of nervous or psychical influence, and hence its cause should be sought out before it is attributed to myocardial degeneration. In fact, we now know that decreased frequency of the pulse is less often indicative of fatty degeneration than was formerly supposed.

Two considerations are worthy of note: (1) Retardation of the pulse due to prolongation of diastole from increased vagus inhibition is very different from apparent bradycardia caused by failure of some, perhaps half, of the heart beats, to send a wave to the radial artery. In the latter condition there are abortive or, as Mackenzie terms them, "the early occurring imperfect systoles" due to defective stimulus or defective response to stimulation. This state of things is therefore serious, and calls for careful comparison on the part of the examiner of the number of cardiac contractions with that of the pulse waves. (2) Bradycardia in a man of middle age is likely to be of far more serious import than in the young, since it may portend cardiac exhaustion. Therefore, when an elderly individual presents slowness of the pulse a careful search should be instituted for signs of arteriosclerosis. If the peripheral vessels show slight thickening or minute points of calcareous deposit and in addition the aortic second sound is unnaturally ringing, there is good reason to suspect chronic myocarditis, whether the heart appears negative or not. Be cautious about recommending such cases, since they are likely to prove disappointing.

As already stated, it is commonly supposed that increase of vascular tension goes with retardation of the pulse, but Rosenbach asserts the contrary to be the case; namely, increased tension with incrased rate, and it has often been my observation that lowness of tension is associated with slowness of rate, and pronounced lowness of blood pressure in a person of middle age in the absence of valvular disease is a sign of cardiac weakness.

The disorders of rate just considered are in themslves sufficiently striking to attract attention at once, but unless very extreme they are not so apt to create alarm as is some disorder of rhythm, particularly intermittence. The rhythm of the pulse may be deranged in any one of three ways. It may be irregular, intermittent, or both irregular and intermittent. Since then so much importance is attached to arrhythmia of the pulse it will be well to discuss these deviations from normal with reference to their causes and relative significance.

By intermittence of the pulse is meant, as everybody knows, a dropping out of a pulse beat at regular or irregular intervals and frequently or infrequently, as the case may be. When it occurs at short intervals it is startling and very likely to create the impression of some serious pathological disorder. Clinical experience, however, teaches that such is by no means the fact in the majority of cases. This conclusion becomes apparent when we consider the mode of its production.

The cardiac muscle fibers possess an inherent or automatic power of contraction, and under the stimulus of healthy blood usually contract with a certain definite rhythm. Nevertheless they are under the control of the pneumogastric nerve, so that if the vagus be stimulated the heart may be made to beat more slowly or even to cease its pulsations altogether. When the heart intermits therefore it is because of inhibitory influence sent down the pneumogastric. Instead of the systoles taking place with accustomed regularity, the diastolic period is now and then prolonged and the expected pulse wave is missed at the wrist.

Such intermissions may occur rhythmically or arrhythmically, yet, in either case they are but the expression of vagus inhibition. This being so, it is plain that intermittence of the pulse does not by any means indicate cardiac disease. Its cause generally, perhaps always, lies in some disturbing factor outside the heart and most often in the gastro-intestinal tract. It may occasionally be due to psychical or nervous disturbance. Some such factor is probably at work when intermittence is observed in young and apparently healthy subjects. When it occurs in the middle-aged it may have the same origin, but it may also be due to the gouty poison, whatever that is. At all events simple intermission of the heart's action is not a sign of cardiac disease in itself. As will be seen later on, however, it has quite another significance when the intermittence is apparent and not actual, that is, is of the pulse and not of the heart.

Irregularity of the pulse is a condition in which the individual pulse waves do not display uniformity in force and volume, but are unequal in size and strength. In this state of things it is found that cardiac contractions are likewise of unequal force. At regular or irregular intervals, as the case may be, feeble or abortive systoles occur which are what Mackenzie termed "early occurring imperfect systoles."

These feeble contractions take place at a shorter period of time than normal after the preceding normal systole and consequently are followed by a corresponding lengthening of the succeeding diastole. The heart does not actually miss beats, but it is irregular in the rhythm of its beats. If now some of these abortive systoles are too feeble to send corresponding waves of blood to the peripheral arteries, then the pulse appears to be, or rather actually is, intermittent as well as irregular in force and volume. This state of things has a very different meaning from mere intermittence. Doubtless irregularity of the heart's action may be due to the fact that the blood is altered in quality or quantity, as in acute infectious fevers without actual cardiac disease, in which case we may conceive of defective or variable stimulation of the cardiac muscle.

But probably these abortive systoles indicate more often some alteration in the muscle fibers themselves, in consequence of which they do not invariably respond with uniform strength and rate to the stimulus applied to them. Therefore it is very common to observe this kind of irregularity of the pulse in mitral disease and in chronic myocarditis when the auricles are degenerated and perhaps distended. It is, therefore, not uncommon in elderly men, with or without other demonstrable evidence of cardiac disease.

These abortive systoles are sometimes the cause of apparent bradycardiac as well as of pulse intermissions, and in any case of abnormal infrequency or of intermittence of the pulse, one should compare the heart beats with the pulse waves by means of auscultation. If they do not agree, be careful how you recommend the person for insurance.

Lastly under this head permit me to call attention to the fact that whenever the pulse grows irregular under exercise it is in all likelihood an indication of myocardial weakness which renders the heart unequal to the strain. Fortunately there are usually in such cases objective signs of cardiac disease which the careful examiner will not fail to detect. It may, however, be of aid in correctly estimating the wisdom of recommending a cardiopath as an underaverage or defective risk.

Finally, let me say a few words concerning the significance and value of pulse tension. The men whom it is most difficult to judge correctly are those of middle age who are well nourished and present the appearance of robust health. They usually have capacious chests and, in some instances, rather too corpulent abdomens. In such cases pay particular attention to the tension of the pulse, for it is often the earliest and the most valuable sign of a state of things which will some day declare itself as serious inadequacy of heart or kidneys, or of both.

If the pulse is firm and strong, difficult to compress, and with it is found a ringing aortic second tone, they furnish good presumptive evidence of cardiac hypertrophy even though in consequence of the voluminous lungs the area of cardiac dulness appears not increased. Remember that high and sustained blood pressure, together with moderate hypertrophy, is in the absence of positive urine findings early, and often conclusive, evidence of a beginning interstitial nephritis. Abnormal pulse tension in an elderly man who lives well is oftentimes an indication of sclerosis of the mesenteric arteries, a condition which is very apt to lead eventually to arterial changes in the aorta and coronaries, in short to the hypertrophy generally associated with chronic myocarditis. For these reasons it is my opinion that an essential part of the paraphernalia of every insurance examiner should be some one of the devices now established as reliable for the clinical recognition of too high blood pressure. The use of a Gärtner tonometer, for example, would save many a dollar to the insurance companies and spare the examiner much mortification.

SOME EXTERNAL DISEASES OF THE EYE DUE TO RHEUMATISM.*

BY RICHARD KALISH, A.M., M.D.,

OF NEW YORK;

PRESIDENT OF THE MEDICAL BOARD AND OPHTHALMIC SURGEON, CITY HOSPITAL; CONSULTING OPHTHALMIC SURGEON TO THE J. HOOD WRIGHT MEMORIAL AND ST. JOHN'S LONG ISLAND CITY HOSPITALS.

The purpose of this paper is to call attention to those forms of external diseases of the eye which are distinctly rheumatic in their origin, although this has not been ascribed as the causative factor. Neither text-book nor medical journal refers to this influence in producing these affections, and, in our changeable climate they are of sufficiently frequent occurrence to merit consideration. Failure to recognize this fundamental condition is responsible for a continuation of painful, sometimes grave diseases affecting even the integrity of the visual organ itself. Many patients with blear eyes, distorted lids with reddened edges and lost eyelashes, spotted corneæ and lessened sight, the unfortunate victims of long-continued and unsuccessful treatment, would have recovered with uninjured or but slightly damaged eyes had the direct cause of the existing malady been known or even suspected. It is not my intention to claim that all of these bad results might have been prevented; but it can be declared beyond the question of a doubt that the large majority of these patients might have had useful vision restored had critical discrimination in diagnosis been exercised. With an

* Read before the Society of the Alumni of City (Charity) Hospital, December 9, 1903.

acute realization of the position that I take I wish to emphatically state my absolute disbelief in the fantastic theory that rheumatic diseases are due to microorganisms, discovered or undiscovered.

The suboxidation theory with its concomitant results of faulty metabolism and increased disassimilation amply explains, except to those perverted by vast excursions into the limitless realms of fancy, the formation without microbic intervention of a chemical poison from whose toxic influence arises the pathological changes and the protean symptoms of that complex which we recognize as rheumatism.

The diseases that will be considered under the title of external diseases of the eye due to rheumatism are: (1) Marginal blepharitis of the young adult; (2) recurrent hordeoli or styes; (3) recurrent chalazia; (4) circumscribed bulbar conjunctivitis; (5) limited circumscribed bulbar conjunctivitis, and (6) striated keratitis.

1. Marginal Blepharitis Occurring in Early Adult Life.—The form of marginal blepharitis with which we are most familiar is that occurring in children up to the age of puberty. This is usually associated with the so-called strumous diathesis, often depending upon some local irritation as its exciting cause. The variety due to rheumatism differs from this in that it occurs in early adult life, from about the eighteenth to the twenty-fifth year, and sometimes continues up to the thirty-fifth year. Like other diseases arising from systemic causes, it is always bilateral from the beginning and unlike this affection in the young there is no involvement of adjacent structures, the inflammation being restricted to the borders of the lids and never encroaching upon the skin or conjunctiva. It likewise differs in the fact that although there may be some photophobia present, and dust and cold wind may cause an annoying and discomforting irritation, sight is rarely interfered with to any extent. The edges of the lids are red, swollen and everted, and there is an increase in the sebaceous secretion which gathers at the roots of the eyelashes and with exfoliated epithelial cells forms scales and crusts beneath which superficial and deep excoriations exist, the healing of which often produces extreme distortion of the lids. Errors of refraction and muscular imbalance, either or both are competent to set up conditions identical with those just described; but examination of sight readily discloses the defects, and properly fitted glasses will overcome these troubles and likewise accomplish much good by serving as a protection against cold winds and dust.

Rheumatic marginal blepharitis is precisely that condition, the determining cause not having been recognized, which authors declare *"to be more or less constant, without known cause and with little possibility of a cure."* Against this etiological agnosticism, and therapeutic nihilism, I must enter a firm protest, for, if optical error when present be corrected, muscular insufficiency overcome and a thorough antirheumatic treatment, medicinal and dietetic, be enforced, rare indeed will be the case that does not respond to treatment and terminate in recovery. Especial stress is laid upon the necessity for an early diagnosis as to the cause of this trouble because of the serious outcome of the unchecked inflammatory process. Neglect to promptly discover rheumatism as the cause will bring about swollen and permanently thickened and everted lids producing ectropium. Or later cicatrical contraction may invert the lids with resultant entropium with misplaced eyelashes curled inward which start up corneal irritation, inflammation, ulceration and more or less dense opacity, giving rise to interference with, or even abolition of sight. Contraction of the lid tissues not infrequently displaces or even obliterates the punctum lachrymale, and constant lacrimation supervenes to the lasting discomfort and annoyance of the sufferer.

Accompanying inflammation of the borders of the lids is a similar condition of the hair follicles, which we call styes. These may occur independently of the lid trouble and are extremely painful, the redness and swelling being very considerable and entirely disproportioned to the extent and gravity of the disease. Styes are not only multiple but often recurrent, and when this happens they are due to the rheumatic poison. Given a recrudescence of styes, some of them abortive—the so-called "blind" styes—and any optical anomaly present having been antagonized by properly adjusted glasses, local irritation from dust, exposure to heat or cold having been eliminated, the cause is rheumatism.

From hordeolum to chalazion is but a step, as the first named is an acute inflammation of the hair follicle and its surrounding tissues, the other a chronic inflammation of a meibomian gland rarely accompanied by pain. Chalazia have heretofore been considered to be retention cysts, the first stage of which was a plugging up of the gland duct and retention primarily of the normal, and then of a changed secretion.

Recent investigations have demonstrated that a true inflammatory process followed or was coincident with the sealing of the gland orifice. As soon as discussion began respecting the etiology of chalazion the wary bacteriologists hunted through their stock of unassigned microorganisms and handed out the *Bacillus xerosis* as the direct infecting agent. This microbe normally exists in the conjunctival sac and until an explanation is offered to account for the change from feeble to stronger pathogenic properties, oculists will be loth to accept this *ipse dixit* as conclusive evidence.

When chalazion becomes recurrent it is distinctly rheumatic in type. This opinion is founded upon clinical experience, which the history of the following case exemplifies:

The patient had submitted nine times to operation for the removal of chalazia and seemed still far from being relieved from further trouble, for three small elevations on his lids were slowly but regularly increasing. He was looking cheerlessly forward to future operations when he was

suddenly seized with rheumatic fever, his initial attack, which confined him to bed for days and to the house for weeks. Treatment was at once employed and on his recovery from the rheumatic attack he found that the lid tumors has entirely disappeared.

A few months later a small chalazion appeared on the lid, antirheumatic treatment was at once instituted and local massage with white precipitate ointment was regularly applied. Complete absorption of the enlargement supervened. The local treatment cannot be held responsible for the cure, because it was employed on every tumor previous to operation and in not one of them did it produce the slightest amelioration. This case is not an isolated one, as equally good results have been obtained so many times that when chalazion takes on the *recurrent* form I insist that antirheumatic medication and regimen be adopted. In the vast majority of cases a cure follows.

Do not infer from what has been said that I hold the rheumatic poison to be the sole exciting cause of chalazion, for such is not my opinion. Mechanical or inflammatory occlusion of the gland duct, cold, dust, burns, chronic blepharitis and optical defects may one or all be named as active participants or predisposing factors in producing this unsightly but innocuous condition. The influences just enumerated having been removed, controlled or eliminated and recurrence persisting, rheumatism is at the bottom of the trouble, and its treatment will eventuate in recovery; but this applies to small and recent growths where there is retention of secretion only, and possibly but slight epithelial hyperplasia. When, however, the tumor is materially enlarged, and is more or less firmly attached to the cartilage, proliferation of connective tissue has been added to altered epithelium and the gelatinous secretion has become purulent or mucopurulent, so that medicinal and dietetic treatment are unavailing, an operation is the only recourse.

There is a form of conjunctivitis rheumatic in its origin, which I call circumscribed bulbar conjunctivitis, the distinctive feature of which is that it is localized to the conjunctiva of the eyeball and never encroaches upon the membrane of the lid. It effects but one-half of the eyeballs and by preference the nasal sides. Since beginning this paper I have seen a case in which the temporal halves almost to the median line were involved. As in other forms of conjunctivitis the blood vessels were enlarged, tortuous, easily emptied on pressure and freely mobile. This type varies from other forms in that the discharge is watery, a mild, not profuse lacrimation, and is never mucopurulent nor purulent. This inflammation comes on without any prodrome, usually during the night, seems to follow exposure to a sudden lowering of the external temperature and must be considered as an occupation disease seeming to attack only those employed out of doors. Engineers engaged in constructing bridges, railways, subways, or electrical enterprises; architects supervising the erection of buildings; pilots and the ubiquitous book agent, seem to be the susceptible ones. My first case happened in the person of an engineer on the electric subway. I saw him three days after the trouble began. The general appearance, pain and inflammation were so acute and intense that a tentative diagnosis of episcleritis was made and treatment at once inaugurated, a strict antirheumatic course being adopted. Within three days the improvement was so conspicuous that only one opinion was tenable, namely, that the conjunctiva alone was affected. A few months later a second attack was experienced. General treatment was instituted within twenty-four hours from the inception of the trouble, no local treatment was employed and in about one week the cure was complete. About six months later his third attack came on, and before his physician reached him he was seized with an attack of acute articular rheumatism involving both knee-joints. There was considerable swelling and the suffering was intense. Before a single dose of medicine had been taken the conjunctival congestion localized to the nasal side of both eyeballs, spontaneously disappeared, and did not return during the course of the disease. It is to be borne in mind that this was his initial attack of rheumatism, for, excepting the two attacks of conjunctivitis, he had been free from any symptoms of rheumatism, never having suffered from even the muscular pains that are so generally experienced.

He has had two attacks of rheumatism since recovering from his first one, but in neither of these latter has there been any conjunctival implication. The appearances in this disease strongly resemble those observed in scleritis, but, being an innocuous ailment, it has none of the sinister portent that accompanies scleritis. Discriminating diagnosis can easily be made, provided the following points be observed:

CONJUNCTIVITIS.	SCLERITIS.
A feeling as if a foreign body were between the lids and the eyeball.	A feeling of fulness in both lids and eyeball, usually beginning in the eyeball.
No special tenderness of the eyeball.	Considerable degree of ciliary tenderness.
Neither elevation nor discoloration of the sclera.	Sclera elevated, the patch reddish in color going over to purplish in the centre.
Enlarged tortuous vessels, freely movable over the sclera and easily emptied on pressure.	Straight vessels like fine red threads in the elevated patch, not movable and but slightly changed in color on pressure. A few large tortuous vessels may be superimposed over the finer ones: this is not constant, but when they are present, the scleral vessels are conspicuous by contrast.

CONJUNCTIVITIS.	SCLERITIS.
Discharge watery.	Rarely any discharge.
Photophobia slight, if present.	More or less photophobia.
Pain, smarting in character.	Dull or aching pain, not neuralgic.

There is a variety of this disease restricted to the conjunctiva directly over the insertion of one of the recti muscles, which simulates scleritis so closely that mistakes in diagnosis are common, but if the points in differentiation just quoted be carefully observed accurate diagnosis presents no difficulty. This is the limited circumscribed bulbar conjunctivitis.

Finally, we come to striated keratitis, a rare disease, but of which I have seen several cases. In its appearance, to the unaided eye, it strongly resembles the striped keratitis that semi-occasionally follows cataract extraction, especially after tardy and difficult removal of the lens. In such cases the appearances are due either to a folding of decemets membrance or of the deeper layers of the flap. In striated keratitis of rheumatic origin the cornea assumes a grayish tint and very shortly thereafter grayish parallel lines appear, bisected at almost right angles by similar lines, producing a checkerboard appearance that is absolutely distinctive. Deep infiltration of the cornea follows, subsequent to which occurs the circumcorneal injection so suggestive of keratitis. At this stage the disease is easily mistaken for parenchymatous keratitis, but treatment applicable to this latter condition is without the slightest response, while a long continued antirheumatic course consisting of salicylates, iodides, baths, massage, etc., will bring about complete restoration.

This brings to a conclusion all that I have to say on the subject of external diseases of the eye due to rheumatism. From this paper has been omitted mention of chronic conjunctivitis of the rheumatic and gouty, corneal ulcers of middle and advanced life, scleritis and the other ocular diseases due to rheumatism, because they are fully described in text-books, whereas those that have been brought to your notice in this paper are conspicuous by their absence, no allusion whatever being made to them. Because of this omission I have brought this subject before you, as I wished to enter an earnest plea for the early recognition and diagnosis of this causative factor, in order that it should receive immediate treatment to prevent damage and in some cases disaster to sight.

36 West Forty-seventh Street.

Glycogen in Leucocytes.—All former theories relative to the presence of glycogen in leucocytes have taken it for granted that the cells of the circulating blood are entirely free from this carbohydrate. A. Wolff (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6) shows, however, that if the vapors of iodine are allowed to act upon a still moist specimen of blood, every normal leucocyte will be found to contain glycogen. This glycogen is extremely soluble, and hence cannot be detected by the usual methods; as soon as the leucocytes leave the vessels it can be demonstrated.

RUPTURE OF THE SPLEEN: REPORT OF TWO CASES.*

BY CHARLES F. CRAIG, M.D.,

OF SAN FRANCISCO;

FIRST LIEUTENANT AND ASSISTANT SURGEON U. S. ARMY; PATHOLOGIST AND BACTERIOLOGIST TO THE U. S. ARMY GENERAL HOSPITAL, PRESIDIO OF SAN FRANCISCO, CAL.

Rupture of the spleen, especially spontaneous rupture, is of such rare occurrence that I have thought that the two following cases occurring at the U. S. A. General Hospital, Presidio, San Francisco, Cal., might be of general interest and should be recorded. As showing how rare spontaneous rupture of the spleen is, especially in this country, Osler[1] states that no case of spontaneous rupture of this organ has been recorded here. The condition is said to be much more frequent in the Tropics, but it is to be noticed that writers upon tropical diseases, such as Manson[2] and Scheube,[3] in their classical works devoted to that subject do not mention this condition. Playfair,[4] however, states that in an experience of two and one-half years in the East Indies he observed 20 cases, but I have been unable to determine whether or no these were spontaneous in character. Strümpell,[5] in his text-book upon medicine, does not consider this subject at all, and Stengel,[6] writing upon the diseases of the spleen, devotes but two pages to this condition. Bovaird[7] cites a case of rupture of this organ in splenomegaly due to a slight fall upon the abdomen.

The condition is said to be most frequent during malarial infections, or in patients suffering from typhoid fever, or relapsing fever, and rare instances have been observed of rupture of the spleen in blood diseases, such as leucemia. I cannot believe that the rupture of this organ is of very common occurrence in malarial infections. The condition has never occurred in thousands of cases of malaria which I have personally observed, and in a study of the estivo-autumnal malarial infections[8] I have mentioned the occurrence of rupture of the spleen, but at the time of writing had never seen or been told of one instance by practitioners in malarial regions. Since then, Assistant Surgeon William P. Banta has informed me of a case under his care in Manila in which rupture of this organ occurred during a malarial infection, probably due to some violent movement of the patient, although this history cannot be clearly proven. That the condition, however, is a rare one, even in malarial infections, I believe there can be no doubt, and this is proven by the experience of lifelong students of malaria, such as Marchiafava and Bignami.[9] The latter authority observed a case in the person of a young man suffering from a relapse of estivo-autumnal malaria, who was suddenly seized with severe pain in the left side accompanied by symptoms of collapse, and ending in death in forty-eight hours. The autopsy showed a slight laceration of the capsule of the spleen, and the peritoneal cavity contained a large amount of blood. The same authorities quote

* Published with permission of the Surgeon General, U. S. Army.

two cases observed by Bastianelli, of patients suffering from pernicious malarial infections. In the first case the patient was brought to the hospital moribund, and at autopsy a large amount of blood was found in the peritoneal cavity and a large clot situated above the spleen. The capsule of the spleen was detached by the coagulated blood, but the laceration was small, and the severe hemorrhage was due to the fact that a medium-sized artery was perforated. In the second case, the patient was brought to the hospital in the same condition, and at autopsy the peritoneal cavity was found filled with blood and a laceration of the capsule of the spleen was found about two c.m. long. An examination of the organs and the blood in both these cases showed numerous malarial parasites of the estivo-autumnal variety.

The rupture may be spontaneous or due to mechanical violence but never occurs spontaneously in a healthy subject. Rupture due to mechanical violence, such as a severe fall upon the side or abdomen, may, of course, occur in health. Laceration of the spontaneous variety may occur at any portion of the capsule of the organ and may be single or multiple. The hemorrhage may be violent or very slight, according as the laceration is slight or severe. The laceration often occurs through the site of an infarct. The effused blood may entirely fill the abdominal cavity or may become encapsulated in the vicinity of the spleen or surrounding organs. Litten[10] describes cases in which the spleen being adherent to the stomach or intestines, and the rupture occurring in the adherent portions, the blood was effused into these organs.

The symptoms associated with rupture of the spleen vary in ratio as the laceration is slight or severe. In those cases in which the tear is of large extent the symptoms are those of a severe and rapidly fatal collapse. In other cases where the laceration may be very slight, the hemorrhage is slow and the symptoms of collapse develop very gradually. There is no reason to doubt that in some very slight lacerations recovery may take place, but in the vast majority of cases the condition is invariably fatal unless proper methods of treatment are pursued. In the two cases I shall describe, so far as the history can be obtained, the laceration was spontaneous. One of them occurred in the person of a patient suffering from typhoid fever. The other, and the most interesting, in a case of primary carcinoma of the liver with metastatic involvement of the lungs. For the clinical history in this case I am indebted to Assistant Surgeon Edward P. Rockhill, U. S. Army.

Case I. Rupture of the Spleen Occurring During Typhoid Fever.—H. W., twenty-three years old, birthplace, New York. Date of entrance to hospital, September 12, 1902. Previous history, not obtainable. The patient was a soldier returning from the Philippines on the U. S. Army Transport "Meade." His present illness began about eight days before admission, with headache, backache, and several slight chills. He stated that he had been feeling badly for about two weeks. Patient was diagnosed on the transport as a case of intermittent malarial fever. Upon admission, the symptoms chiefly complained of were headache, severe diarrhea, and tympanitic abdomen. The blood was examined September 12, 1902, and found negative for malaria. On September 15 Widal's reaction was requested and found positive, with a dilution of one in forty, in ten minutes. From this time until October 3 the patient ran a typical course of typhoid fever, and at this date his temperature had reached normal. In the clinical notes of the case on October 3, it is stated that that morning the patient felt cold and sleepy. His temperature became subnormal and there was slight delirium. On October 4, the temperature having remained subnormal, the patient complained of severe pain over the abdomen, especially in the left hypochondrium. This pain increased during October 5 and the patient presented all the symptoms of collapse, but not of very severe character. This condition persisted until October 7, when he became rapidly weaker during the afternoon of that day and complained of very severe pain over the whole abdomen. After six o'clock in the evening he became comatose; the pulse was imperceptible, the skin bedewed with cold perspiration, and death occurred at 11:40 P.M.

Autopsy.—Body considerably emaciated; rigor mortis, medium; finger nails congested; slight ante-mortem discoloration over the chest and abdomen; slight post-mortem discoloration over the dependent portions of the body; pupils slightly dilated, the right being the larger; finger nails slightly congested; weight, 110 pounds. *Abdominal cavity.*—Upon opening the abdomen the greater omentum was found adherent to the coils of the intestine by lymph and the small intestine was greatly dilated with gas and covered with purulent exudate. The coils of the intestines were adherent to one another. The abdominal cavity contained a considerable amount of purulent exudate. The appendix lay on the brim of the pelvis and appeared inflamed. The mesenteric glands were greatly enlarged. Upon removing the intestine in the region of the spleen, a large amount of blood was found confined to the region immediately surrounding the spleen, and upon examination of that organ a large laceration through the capsule was discovered at the lower portion, measuring about 3 cm. in length. The injury, however, was not confined entirely to this laceration, as the capsule of the spleen was removed over an area measuring 3 by 6 cm. and there was considerable laceration of the splenic substance. The organ measured 20 by 11 cm., was externally dark reddish-purple in color and the capsule was slightly wrinkled. Upon section, the surface was of a dark mahogany red color, the Malpighian corpuscles being indistinct. The organ was very greatly congested and it was found that the laceration extended for a distance of 1 cm. into the substance of the organ. The

pathological lesions found in the other organs were those common to typhoid fever. The large intestine showed a few old ulcerations, evidently dysenteric in character, which were almost healed. The ileum showed numerous typical typhoid ulcerations, and it was noted that some of these had nearly perforated, extending to the serus coat of the intestine.

This case is interesting in that the rupture was without doubt spontaneous, as the patient was so ill, having suffered a severe and long-continued typhoid infection, that he was confined to his bed and kept very quiet. It is hard to say just when the rupture occurred, although it is probably at the time he first complained of the severe pain in the side. The collection of blood would without doubt have become encapsulated had the patient survived long enough, and as it was, it was localized entirely in the region surrounding the spleen, there being no free blood elsewhere in the abdominal cavity. The question arises as to the etiology of the peritonitis which was present. It may have been, and probably was, due to the effusion of blood into the peritoneum, but it might have been caused by the extension of bacterial infection from the intestine, as several of the ulcers were simply separated from the abdominal cavity by the exceedingly thin serous coat of the intestine. Cultures were made from the spleen and resulted in a pure growth of the typhoid bacillus.

For the clinical history of the second case I am indebted to Dr. T. J. Strong, U. S. Army.

Case II. Rupture of the Spleen Associated with Primary Carcinoma of the Liver and Metastatic Carcinoma of the Lungs.—J. C., sixty years old; birthplace, Ireland. Date of entrance into hospital, February 6, 1903. History previous to admission presented nothing of interest beyond the fact that patient had suffered from malarial fever for fifteen years and had used alcoholics for twenty-five years. His present illness he dated from December 2, 1902, and claimed that it resulted from a fall which he received at that time. At any rate, he had been sick since this fall. Upon entrance to the hospital patient was found to be emaciated and complained of severe vomiting and pain in the right side below the ribs. He had almost complete anorexia. Upon examination it was found that he had severe edema of the abdomen, and that the liver reached six or eight inches below the ribs. The examination of the blood was negative, as was also that of the urine. From his alcoholic history and the enlargement of the liver, the case was diagnosed as chronic hypertrophic cirrhosis of the liver. During his stay in the hospital his symptoms were chiefly those already enumerated, *i.e.*, great weakness, anorexia and vomiting. Upon March 5, at 5 A.M., it was noticed that his breathing had become somewhat difficult, and death occurred very suddenly.

Autopsy.—Body considerably emaciated; skin of a yellowish color; rigor mortis absent; marked post-mortem discoloration over the dependent portions of the body. *Thoracic and Abdominal Cavities.*—Upon opening the abdominal cavity, it was found to be filled with blood. The liver reached 11 cm. below the border of the last rib and extended entirely across the abdomen, and was so large that it severely compressed the stomach and the spleen. Upon examination of the latter organ, a laceration of the capsule was found measuring 9 cm. in length. The stomach, pancreas, spleen and intestines were bathed with blood which had escaped from this laceration. Upon removing the organ it was found to measure 15 by 10 cm. The capsule was smooth and the organ a dark purplish-red in color externally. The laceration was situated along the upper border, and upon examination this portion was discovered to be involved in a large red infarct through which the laceration had occurred. A cyst was found closely associated with this infarct, measuring 1 cm. in diameter and filled with blood, thus showing that previous hemorrhage had occurred within the parenchyma of the organ. The consistence of the organ was almost diffluent.

Liver.—Considerable difficulty was experienced in removing the liver as it was adherent to the diaphragm, the stomach, and the spleen, and was so large as to almost fill the upper half of the abdomen. Upon examination the capsule was found to be smooth, although there were small nodules discretely scattered over it. Upon section of the organ, four large tumor masses were found which presented the typical appearance of carcinoma, the largest of these masses measuring 15 cm. in diameter. Only a small part of the liver tissue was not involved in the carcinomatous process. *Stomach.*—The stomach showed a very severe chronic gastritis, but there was no indication whatever of malignant disease, although this was looked for very carefully. The small intestine appeared normal save for intense congestion. *Pancreas.*—The pancreas was considerably congested, but otherwise normal. *Left Kidney.*—The left kidney measured 13 by 5½ cm. It was much congested externally. The capsule was smooth, there being no evidence of cystic formation. Upon section, the cut surface was found to be greatly congested. The cortex and pyramids were indistinct and the cortex thinner than normal. The mucous membrane of the pelvis was also much congested, and the consistence of the organ was increased. The capsule was not adherent. The right kidney presented the same appearance as the left. *Heart.*—The heart appeared normal. *Lungs.*—The pleural cavities were free from fluid. The left lung was adherent to the chest wall over its entire surface by old adhesions. The lung was crepitant in places but had a nodular feel. Upon section of the organ, it was found filled with small tumors, the largest not measuring over 1 cm. in diameter, and upon section these little masses presented the typical appearance of metastatic carcinoma. The right lung was adherent to the chest wall over its entire surface by old adhesions. The pleura was greatly thickened, and upon section the entire organ was

found invaded by metastatic growths which were evidently of carcinomatous nature. In both organs the small tumors showed here and there through the pleura.

Upon microscopical examination of sections from the tumors of the liver and lungs they were found to be of typical carcinomatous structure.

This case is of great interest in that it showed two very rare conditions: First, primary carcinoma of the liver; and, secondly, rupture of the spleen. The primary growths of the liver occurred in the form generally described as the massive form of primary carcinoma, and a study of the microscopical sections showed that there had been previously, without any doubt, a severe cirrhosis of the organ. The rupture of the spleen was, I believe, due to the pressure upon it of the greatly enlarged liver. That it was spontaneous —in the sense that it was not due to sudden movement—is, I believe, true, because the patient was so ill that he could hardly move in his bed. The substance of the spleen was very much decreased in consistence, and the fact that there was a large infarct just beneath the laceration, which involved it, would conduce to the occurrence of rupture by pressure, as the capsule over this infarct was much thinner than normal. In my mind, there can be no doubt that the spleen became wedged between the wall of the abdomen and the liver, and that the growth being gradual, the pressure hindered circulation in the upper portion of the organ, thus causing the infarct, and with this pressure continuing, a rupture occurred. I believe this is the only case on record in which rupture of the spleen was produced in this manner. The clinical symptoms in this case varied greatly from the one just previously described in that death was due to the enormous amount of hemorrhage from the large laceration, which took place suddenly, and caused almost instant collapse; whereas in the first case the laceration was of less extent, the hemorrhage more gradual, and the effusion of blood localized, thus prolonging the patient's life.

Microscopical examination of sections of the spleen in both cases did not show anything of interest beyond intense congestion, and in the latter case the ordinary pathological lesions of red infarct.

In closing, I would call attention to the great dificulty of diagnosing this condition. In the first case described the collapse would undoubtedly have been attributed to late perforation in typhoid, while in the latter case the condition was so rapidly fatal that the diagnosis could not have been reached. In cases of malaria, however, in which there is sudden or gradual collapse, a diagnosis could be more easily made, and this condition should always be thought of should such symptoms develop. It is safe to say, however, that very few cases of rupture of the spleen are diagnosed before death.

SOME FEATURES OF RENAL TUBERCULOSIS.

BY F. TILDEN BROWN, M.D.,
OF NEW YORK.

In this brief paper I shall outline for our discussion the aspects of diagnosis and treatment of renal tuberculosis and shall aim at presenting the diagnostic features in relatively early cases.

The history alone in the case of any new patient is ordinarily enough to awaken suspicion that we are dealing with the disease under consideration. The answer to our first question, "Of what do you complain?" is usually sufficient to give a clue when the patient replies: "I am annoyed by passing my water so often." Tabulating the anamnesis of this patient in regular order, its review, together with fifteen or twenty others where the same disease has existed, will afford a composite picture of the following sort:

The patient is a male or female, of an age from twenty to thirty-five years. The family history shows that one or the other parent died of consumption. Not unlikely a brother or sister has or has had some of the chronic manifestations of tuberculosis. The personal history tends toward revealing a past story of more or less ill health, although exceptions to this are noticeable. The present complaint dates from and is remembered in association with some prolonged muscular effort where exposure to wet or cold occurred at the same time, more or less of a chilling resulted, followed by some fever, and the first frequency of micturation was then noticed. Many of the cases had, a few months before, met with a fall or some kind of injury involving one or the other lumbar region, and the place has been somewhat sensitive ever since. When the patient was first bothered with frequency, this symptom lasted only a week or ten days, followed by a seemingly normal condition of the bladder. Another attack, some two months later, associated with mild fibrile state, malaise, and loss of appetite, led the attending physician to diagnose malaria and treat the case as such. After improvement in the constitutional symptoms, the pollakiuria this time continued longer than before, and the patient now for the first time paid some attention to the appearance of the urine, as it was caught in a glass vessel; the fluid in the majority of cases had a mild opacity, like milk-tinted water, in a few instances the patient observed, a slight reddish tinge which suggested a possible admixture of blood. There was never any real pain connected with urination, but a moderate intimation of discomfort in the suprapubic region, and the annoyance of having to get up at night for micturition, which was just as compulsory at regular intervals as during the day. A very few of the

patients have at times had such severe pain in the loins and down the side, accompanied by nausea and vomiting, as to make their medical attendant diagnose renal colic of calculus or gravel origin. The degree of pollakiuria in the majority of the patients amounts to emptying the bladder every two hours.

We are now ready to make our own observations in any of the foregoing cases. It is seen that the patient is usually poorly nourished, but even if rotund and well muscled the color is faulty. Temperature is a degree or so above the normal. Bimanual palpation over the loins gives a tenderness on one side or the other, even if the kidney is not palpable. In the female cases we do not attach too much importance to the presence of a palpable and tender kidney on the right side, even after we have established the diagnosis of urinary tuberculosis, for the left organ may be the seat of the disease and yet not palpable nor so tender as is the commonly prolapsed but otherwise healthy right gland.

Instead of being satisfied with the urinary specimen which the patient has perhaps brought, request is made that the bladder be now emptied in two glasses. This gross inspection of the just voided fluid may be of considerable value in supporting our suspicions as to the nature of the case with which we are dealing. At any rate we do not fail to examine microscopically a drop of the sediment in the fluid state. If every field is made up of few or many leucocytes with practically no other ingredient, and particularly if micro-organisms are conspicuously absent, the suspicion of tuberculosis is increased. Several slides of the sediment are now dried and stained for tubercle bacilli. If in the faintly blue field we find an occasional minute granule holding the red fuchsin stain, whatever these spore-like bodies are, they may reasonably serve to encourage the expectation that ere long two or three typically arranged tubercle bacilli will be met. When found we may be pretty sure of the diagnosis, but before risking the announcement to the patient it is well to get another specimen by means of a sterile catheter and thus avoid a possible contamination of the urine by the smegma bacillus which tends, both morphologically and in the staining reaction, to resemble the tubercle bacillus. On again finding the same microorganisms after such exclusion of smegma bacilli we are prepared to tell the patient that it is necessary to determine the source or sources of these consumptive germs, for as yet we are wholly unable to give advice as to future treatment, not knowing whether the bacilli come from a vesical or renal lesion, and if of the latter origin, from which side.

The fact that one kidney is palpable and tender does not justify the conclusion that it is the seat of the disease. To determine this question the catheterizing cystoscope is brought into use. Up to this point we have been depicting the physical signs and symptoms of a renal tuberculosis which started in the cortex or parenchyma of the gland, in other words a tuberculous implantation of hemotogenous origin, and not the much rarer form of the disease where a tuberculous pyelitis or pyelonephritis, secondary to ureteric extension of a bladder tuberculosis, has occurred. Consequently the conditions to be expected when we now employ the catheterizing cystoscope are those which go with the mildest sort of tuberculous vesical involvement if any. Even here the bladder is at best somewhat hyperesthetic and as generous an anesthetization with cocaine or eucaine as is consistent with safety should be employed.

The limits of this paper will not permit us to consider even a few of the many interesting points connected with the technic of this examination test, nor the various conditions which the bladder may present. It must suffice to allude to that almost pathognomonic appearance of the ureter mouth, which was first graphically described by Willy Meyer as accompanying a renal tuberculosis on the same side. This consists of an odematus pouting or even a prolapse of its mucous membrane with more or less erosive and hyperemic lesion on part of its periphery. But I have had occasion to demonstrate in two cases that the ureter mouth associated with a tuberculous kidney may appear as normal as its fellow. Occasionally a turbidity, due to blood or pus, can be noted in the fluid issuing from the ureter. But of vastly more importance in reaching a positive diagnosis and of gaining an operative prognosis is the evidence to be derived from examination of the separate urines of the two kidneys. And this is secured by the ureter catheters which are now inserted by the same instrument. The eye of each catheter rests at a point about two inches within the mouth of its respective ureter.

We shall be obliged to pass over the varied behavior of the normal and the diseased kidney during the collection of their excretions, remarking only that the fluids seen in these collecting bottles here attached to the cystoscope represent the gross appearances and show the contrast ordinarily met in synchronous ureter catheterization, where one kidney is healthy and the other the seat of tuberculosis.

If up to the time of this test, despite suspicions of renal tuberculosis, all previous examinations of the voluntarily voided urine have failed to show tubercle bacilli, it is now well to allow some drops of urine from each ureter catheter to fall into separate culture tubes of different media, and also, to collect enough additional urine from each gland to permit of guinea-pig inoculations.

When the diagnosis of unilateral renal tuberculosis is satisfactorily established and evidence of similar foci in other organs is absent, the most debated question, namely, that of treatment, is now to be met. We must here be content with the brief and general statement that for the majority of cases the best outlook lies in a nephrectomy and, if possible, a change of air and an improved hygiene of a month or two should anticipate the operation. In exceptional instances much more extended resource to the same measures and periodical oversight by the same medi-

cal adviser may very rarely be attended by the happy results of a disappearance of tubercle bacilli and all the original symptoms.

Nephrectomy for tuberculosis should always be done extraperitoneally, no matter what incision is selected to approach the kidney. Different indications, such as the size and position of the organ, as well as conformation of the patient in individual cases, besides the views of different surgeons as to how much or how little of the ureter is to be removed with the kidney, are the determining factors in regard to whether the incision be a lumbar, an anterior vertical or a subcostal one. Again various combinations of any of the three are also commonly employed. Briefly stated it may be said that the first mentioned operation is suited to small kidneys, where only an inch or two of the ureter will be removed; that the second supplemented by more or less of a right-angled cut extending outward is well adapted for ureteric management; and the third meets the requirements in many average cases. The two last mentioned incisions do away with the necessity of maintaining the patient in a flexed lateral posture where the well kidney is sure to be more or less compressed by the body weight against the underlying sand bags or air cushions. Whatever incision is employed, after the cutaneous and muscular wound is well advanced and all vessels ligated, the transversalis fascia is severed at the posterior angle of the wound, the perirenal fat appears and two fingers are inserted and directed anteriorly to strip the parietal peritoneum so that it falls toward the median line, the knife follows at a safe distance from this receding tunic. The ureter is now sought by the finger and its condition tested. In the majority of cases its division three inches from its renal attachment will suffice.

To prevent tissue soiling when this is done gauze is led under the duct about which a single ligature is now tied on its renal side, while a pair of pressure forceps are applied to its periphery on the vesical side. The soiled scissors are discarded after cutting the ureter, between the ligature and forceps, and the mucous lumen of both ends cauterized, that of its distal end is cauterized to the distance of half an inch or more, by insertion of the small platinum point. If not easily accessible for the actual cautery, a small swab, moistened with a strong carbolic solution, is twisted into the ureter for a short distance. I generally use a very small curette for denuding the mucosa of the distal end. After the lining has been treated, by any of these means, so as to insure a subsequent coalescence of the tube at or below the point of ligature a knot of chromicized catgut is tied. I am well satisfied that when extra precautions of this kind are not taken to secure adhesive occlusion of the ureter, the ligature alone will prove inadequate in preventing leakage upward from the bladder in fully thirty per cent. of nephrectomies. We have been too prone to ascribe to the vesical outlet of the ureter great sphincteric powers. While such a muscular mechanism may pertain and be thoroughly adequate in the normal organ the vast majority of cases requiring nephrectomy for disease have a corresponding ureter which has undergone pathological changes at some point in its continuity, most probably at its vesical termination, as can so commonly be seen at the time of a preliminary cystoscopic examination.

The ureter having now been disposed of, the remaining part of the pedicle receives attention. When accessible for the purpose separate chromicized catgut ligatures are placed upon the large vessels, and the kidney cut loose. Not uncommonly the size of the kidney and its liability to rupture, or the indurated condition of the attached part of the ureter, will make it easier to seize the pedicle as a whole, with one or several clamps, then cut the kidney free before isolating the vessels for ligation. Under such circumstances, however, although the space occupied by the kidney has been gained, the marked retractile tendency of the pedicle besides being more or less anatomically distorted and concealed by the clamps, makes separation of the vessels for ligation now quite as difficult as before. Since the renal artery can nearly always be readily identified by its pulsation, I like to get a well-placed ligature at least on this one vessel before separating the kidney, even if the other vessels are intrusted to clamps until after the kidney is detached.

HOOKWORM DISEASE AND MINERS' ANEMIA IN THE ANTHRACITE COAL FIELDS.*

BY JONATHAN M. WAINWRIGHT, M.D.,
OF SCRANTON, PA.,
AND
HENRY J. NICHOLS, A.B.,
OF THE UNIVERSITY OF PENNSYLVANIA.

It has been known for a number of years that there is a certain severe and widespread disease among European coal miners, known as miners' anemia, which is caused by the intestinal parasite, *Anchylostoma duodenale* or hookworm. The disease is, therefore, communicable and in some mines has spread to 95 per cent. of the men employed.

So much has recently appeared in American medical literature on the general aspects of hookworm disease, on its mode of spreading, and its symptomatology, that in the present contribution only those phases of the disease especially connected with mining will be taken up.

The old world variety of the parasite was discovered in Italy by Dubini in 1843. A short time afterward, the worm was shown to be the cause of the so-called Egyptian chlorosis and, later still, to be the cause of an epidemic anemia in Brazil. The disease, however, did not attract much attention until work was begun on the St. Gothard tunnel. Here it was observed that the

* Studies from the clinical laboratory of the Moses Taylor Hospital.

Italian workers in large numbers suffered from a disease marked by anemia and general debility by which many were incapacitated for work. Perroncito and others investigating this malady found that it was due to this same parasite of Dubini and that the tunnel workers were infected to a very large degree. In a few years it was spread by returning workers all over Italy.

These Italian laborers are supposed to have first carried the disease into the Hungarian coal mines. Here it spread until at present in some of the mines, as for instance in the Chemnitz district, 95 per cent of the miners are infected. From Hungary, the disease spread to Germany. It is said that in the district of Westphalia there are about 25,000 miners affected. At a meeting of miners' representatives from all coal-mining countries of Europe, held in Brussels in 1902, this subject was especially discussed by the German delegates, who claimed that, as the result of the ravages of this parasite, the average duration of a miner's life has fallen from forty-five to forty years since 1896.

From Germany, the disease is supposed to have reached Belgium. Romme[1] states that in Belgium the Institute Bacteriologique found that among 10,000 miners examined, 55 per cent. were infected. The affection has been so serious in Belgium that at Liege it has been found necessary to establish a special dispensary for the treatment of anchylostomiasis. This, with improved sanitary arrangements at the mines, has considerably reduced its prevalence in this country.

In France, the situation is a little less clear. Breton,[2] of the Pasteur Institute of Lille, states that in the Loire basin five per cent. of the miners are infected and at St. Etienne about two per cent. Breton further makes the interesting statement that Halle in 1802 described an epidemic form of anemia among the miners at Anzin, France, which corresponds exactly to anchylostomiasis. It was attributed to bad ventilation. In 1875, a medical society in the Loire basin also investigated a form of anemia and came to a like conclusion. Riembault,[3] too, writing in 1861, described a disease closely resembling anchylostomiasis which he called *anemia d'Anzin* and considered to be epidemic. Breton believes that the extent of the disease in France was formerly much greater than at present, and that it has been reduced to the proportions he indicates. Recently, however, the French Service des Mines stated as a result of an inquiry of their own that the disease is not present in the French mines. This conclusion seems improbable and is discountenanced by Breton.

In England the situation is very interesting. Boycott and Haldane[4] have investigated a widespread form of anemia present in the Dolcoath mine in Cornwall. These observers consider that practically all of the seven hundred underground workers are infected with anchylostoma. They found the ova in the stools of 38 out of 46 miners examined. They believe that the disease was introduced into the Dolcoath from the Colonies, probably South Africa, and that it has been spreading through the mine for about eight years. The Dolcoath is a metalliferous (tin) mine, but the physical conditions, so far as this worm is concerned, are practically the same as in coal-mines. Thorough examination of other mines in England have not as yet been reported.

Stockman[5] reports a case in a coal-miner, in Lanarkshire, Scotland. This man had previously served two years in the army in India, and undoubtedly contracted the disease there.

The spread of this parasite through mining regions is easily accounted for by the life history of the worm itself and the sanitary conditions favoring it in practically all mines. The infectious material is of course fecal matter. This in many cases contains innumerable ova. When the fecal matter is deposited on the ground under favorable conditions, the ova develop into larvæ which are infectious for men. These larvæ when taken into the mouth develop again into the adult organism. There are certain physical conditions for the development of the eggs which the mines supply very nicely. The eggs require a temperature of 20° to 40° C. and a certain amount of moisture. Bruns[6] has shown that in German and Hungarian mines where the underground temperature is from 25° to 30° C. the disease is prevalent. In other mines having a temperature of 19° to 20° C., the disease is very infrequent or entirely absent. The temperature of our anthracite mines generally ranges from 25° to 40° C. The coal dust lying in the mines forms a very good material in which the eggs can grow. In fact, Goldman[7] and Loos, quoted by Goldman, used coal dust or charcoal to develop the ova experimentally.

The peculiar sanitary conditions which favor the spread of the parasite are these. None of the anthracite mines in this country and only a few coal-mines in Europe, have any privy facilities under ground. The men deposit their excreta in any chamber or gangway handy. If any of the men have the disease, the eggs in their feces will develop, and another man stepping into this material will get some of the infectious larvæ on his boots and transmit them to his hands and then to his mouth. Or, a man can directly contaminate his hands while at work and easily transmit the larvæ to his food, especially if, as is often the case, the worker eats his dinner in the mine, without, of course, washing his hands. The man may not only infect himself in this way, but also may take home the infectious material to his family, as has frequently been observed in Europe. In many of the European mines where ladders are still used to a considerable extent, the possibility of infection is very intimate. A miner walking in infected fecal matter scrapes it off on the rounds of the ladder as he ascends and another miner directly soils his hands in climbing after him. In our anthracite mines, ladders are very seldom used, so that this one element of danger is not present. There is considerable evidence now that the larvæ some times gain en-

trance through the skin. If this mode of infection is possible, it is not the important one in the case of miners.

While several American clinical observers have described a form of anemia closely corresponding to that caused by this parasite, it was not until 1893 that Blickhelm first recognized the true nature of a case in the United States. From this time up to 1892, about 35 cases had been recorded, according to Stiles, in various parts of the United States, some being found in northern cities, such as Philadelphia, Albany, Buffalo, and St. Louis. It was not until 1902, however, that Charles Wardell Stiles,[8] of the United States Public Health and Marine Hospital Service, showed by a series of interesting observations that the disease is very widespread in all our Southern States and that it is due to a different variety of the same parasite that causes the disease in Europe. This variety Stiles had discovered a short time previously and called *Uncinaria Americana*. Further reports now show that the disease is also very widespread in Porto Rico, Cuba, the Philippines and Hawaii.

The wide extent of this disease, then, in foreign coal-mines, in our Southern States, and in our insular possessions makes an inquiry as to its presence in our own coal-mines of some importance. Stiles apparently first drew attention to the great economic meaning of this parasite which won for it in the lay press the somewhat significant title of the "bacillus of laziness." He showed how marked an influence this blood-sucking parasite must have on the productive power of a large portion of our Southern whites. This factor is already being felt in European mines and if this disease is present or threatens our coal-mines its economic importance is great.

We have, then, a disease which tends very particularly to spread through mines, and one which is already very prevalent in countries from which many immigrants come directly to our coal-mines. Further, we know that the disease is widespread in our own Southern States and that it is sometimes found, generally in imported cases, in our Northern cities. Sonsino, quoted by Perroncito, gives 50° 31′ north and 30° 5′ south latitude as the limits in which the disease may be found. Furthermore, it is very prevalent in our islands and is frequently brought to us by returning soldiers. Garrison, Ransom, and Stevenson,[9] found the hookworm in 10 out of 59 examinations of returned Philippine soldiers. The same may be said of the soldiers returning from Porto Rico. Ashford and King[10] consider that 90 per cent. of the agricultural people and 50 per cent. of the city dwellers in Porto Rico have hookworm disease.

Goldman and Bruns have shown that the worms live in their human host for an average of six years, so that for this time every infected immigrant or returning soldier is a possible focus of infection.

It is evident, then, simply from this brief review of the literature of the subject, that, if this disease has not already spread among our coal-mines, its introduction is only a question of time. Stiles has already found one case in a miner in South Carolina. This case, however, does not throw very much light on the disease as connected with mines as the worm is so generally distributed in this State.

In order to obtain some definite information on this subject, we have examined the stools of 400 anthracite mine workers. These specimens have been collected from such widely separated cities as Scranton, Carbondale, Forest City, Pittston, Wilkesbarre, Kingston, Sandy Run, Hazleton, and Lansford. At fifteen mines from 10 to 40 specimens were examined, while the rest were from single cases, as they were found in various miners' hospitals, and therefore widely scattered through many mines. The nationalities examined included all the mixed population found in our coal fields, *i.e.*, Welsh, German, Hungarian, Italian, Russian and German Poles, Lithuanians, Magyars, Slavs, etc. The usual technic for this work was followed—ten cover slips being examined in every case before a negative finding was accepted.

Out of all this number (400) the hookworm ova were found only once. This case was a miner in Scranton, but, unfortunately, through a mistake in labels made by one of the miners, the man himself could not be traced. Stiles, who kindly examined this specimen for us, considered that the ova belonged to the old world variety. Fifty other men were examined at the same mine with negative results.

Another almost equally important finding was the larvæ of *Strongyloides intestinalis, i.e.*, the organism of Cochin China diarrhea. This occurred in a native of Russian Poland in our own wards. He had been a farm-hand in the old country and had been in the United States only a few days before an accident brought him to the hospital so that the organism must have been imported with the patient. He was also infected with *Ascaris lumbricoides* and *Trichuris trichiuria*. He had no anemia or history of diarrhea. This is, so far as we can discover, the first time that either the hookworm or *Strongyloides intestinalis* has been found in the anthracite coal fields. Boggess found the ova in an Italian brickmaker, who had been working in the soft coal fields of Pennsylvania for one month.

The exact clinical and economic singificance of *Strongyloides intestinalis* has not been made out. Perroncito[11] and others frequently found the organism among the workers at the St. Gothard tunnel, both alone and associated with *Anchylostoma duodenale*. Perroncito was of the opinion that the *Strongyloides intestinalis* could of itself produce an anemia. Thayer considers that this idea is disproven and that the parasite may, under certain circumstances, infest man with no harm, while, under other circumstances, it may cause a chronic, wasting diarrhea.

Our knowledge of *Strongyloides intestinalis* in the United States is very limited. It was not until 1901 that Thayer[12] reported the first three cases

found here. Moore described what he considered the fourth case in *American Medicine*, for May 30, 1903. Brown, however, had published an account of three other cases in the *Boston Medical and Surgical Journal* for May 28, 1903. During the year 1903, a number of other cases were reported in the United States, and it is very probable that the parasite is much more widespread than has formerly been considered the case.

It is of interest to note in passing that, among the 400 miners examined, we found 44 different parasitic infections, as follows:

Hookworm	1
Ascaris lumbricoides	15
Trichuris trichiuria	24
Oxyuris vermicularis	3
Strongyloides intestinalis	1
Total	44

This infection was distributed among 37 individuals, as in seven the ascaris and trichuris occurred together. This figure, about ten per cent. of cases, is about the same as Garrison, Ransom, and Stevenson found among soldiers before the Spanish War and is probably a fair average for a working population. The incidence of parasites, however, varies in different nationalities. Thus, of six Italians, railroad laborers at Scranton (not included in the above 400), all were found to harbor parasites, two having *Ascaris*, two having *Trichuris*, and two having both. Recently, an Italian in our wards was relieved of eight round worms and also contained the *Trichuris*. It is probable that, in general, infection with *Trichuris trichiuria* is slightly higher than here shown, as the ova are often very scarce. In some cases, we found only one or two ova in ten slides examined. The ova of the round worm on the other hand are generally so numerous as not to be easily overlooked. In one case we counted 49 round worm ova under a three-quarter inch cover glass. In our own hospital wards, containing as they do a very large foreign element, we can demonstrate a case or two of round or whipworm nearly any time we so desire.

So far, then, as this inquiry has gone, it would show that the hookworm has not obtained much foothold among our anthracite miners, although its presence to a certain extent is demonstrated. The material so far collected, however, does not allow of a definite knowledge of the facts. Hence a much wider search is being carried on. It is possible, of course, as the work progresses, that a single mine may be found, as the Dolcoath mine in England, where the disease has spread extensively and where remedial measures will be necessary.

One interesting finding in this connection is the fact that practically all the mine mules are infected with an organism so closely allied to the human parasite that it can be inferred from its constant presence in mules that our mines present favorable conditions for this family of worms. It is not probable that the mule organisms are transferable from the animals to men. We have not succeeded in infecting guinea-pigs with this worm from the mule, and we have examined five mine-rats' stools without finding anything except a variety of tapeworm.

In any event, the danger of this disease coming into our coal-mines is great, and, when once established, its effect on diminishing the earning power and probably also reducing the average length of life makes it a very important question, for both miners and employers. However, no aid in keeping out the disease can be expected from the miners. Many individual workers have strongly objected to the present inquiry among them and have refused to send specimens. And, too, our miners are so negligent of the rules to prevent the most immediate serious accidents that they cannot be expected to interest themselves in the prevention of a disease so unsubstantial that even a physician has to use a microscope to find it.

The only way probably by which the disease can be kept out of anthracite mines is, as has been suggested by Stiles, for either the State Bureau of Mines or Health to have the stools of newly employed miners carefully examined. The expense of this method will probably prevent its ever being employed as a distinctly prophylactic measure, though the serious economic loss to the state when the disease does become extensive would amply justify it.

We wish to thank Dr. Stiles for verifying our finding of the hookworm and *Strongloides intestinalis*.

The American and foreign literature on *Anchylostoma* is now very large. Appended are a few references of more importance in regard to the mining industries.

Bubonic Plague Spreading.—The bubonic plague is spreading in an alarming fashion along the west coast of South America. The State Department received a cable dispatch last Wednesday from United States Minister Wilson at Santiago de Chili, that the plague had broken out at Antofagasta. This is one of the most important shipping ports on the west coast north of Valparaiso. The Public Health and Marine Hospital Service will be advised, so that suitable precautions may be taken at quarantine.

WHEN AND HOW SHALL WE OPERATE FOR OBSTRUCTING HYPERTROPHY OF THE PROSTATE GLAND?*

BY PAUL THORNDIKE, M.D.,
OF BOSTON, MASS.:
INSTRUCTOR IN GENITO-URINARY SURGERY IN THE HARVARD MEDICAL SCHOOL, ASSISTANT SURGEON, BOSTON CITY HOSPITAL.

As a discussion on the treatment of the various phases of obstructing hypertrophy of the prostate gland is the evident purpose of this meeting, it has seemed to the reader that he can perhaps do his share in opening such a discussion, in no better way than by presenting a brief formulation of his own experience and beliefs relating to the question under consideration. Such a brief résumé is all that this paper will attempt, and it has seemed best that he shall confine himself to a consideration of the indications for the various forms of treatment, making little reference to the technic of the various operative procedures at our disposal. The title of these remarks, therefore, is, "When and how shall we operate for obstructing hypertrophy of the prostate gland?"

In the first place let us consider the "when." As far as prostatic surgery is concerned the last decade seems to have been an era of technical progress which has resulted in the development of a variety of operative procedures, and it may now fairly be said that not only are operations for the radical removal of obstructing prostatic masses easily possible, but that they are possible with a surprisingly small traumatism to structures contained in the prostate gland and contiguous to it. If the literature of these years may be taken as an indication of the trend of progress, it at least surely indicates that such progress has been along the line of surgical technic, and after reviewing it, one might almost be excused for inferring that all prostates ought to be removed after the onset of troublesome symptoms, with the same prompt alacrity which characterizes our attitude toward the troublesome appendix. This is, of course, far from being the case, and even the most radical among us will probably, up to a certain point, concede to the catheter much the same place in prostatic therapeutics which it has always held. Its usefulness is as great as ever, greater, in fact, for its better construction and its more varied form make its possibilities for palliation more extended than ever before; and it probably meets the necessities of a wider range of prostatic sufferers than is palliated or cured by any other one procedure. This I believe to be true now, and probably always will be true.

The catheter is useful "up to a certain point." Then its further use becomes abuse, and unnecessary abuse, for the last few years have developed for us various measures which render such catheter abuse no longer necessary, as it was a quarter of a century ago. Where, then, is that "certain point" up to which the catheter is useful? There is a class of prostatic patients in whom the obstruction has reached a point where it is necessary to empty the bladder one or more times daily, and yet where, because of the patient's ignorance or of the lack of decency and cleanliness in his surroundings, it seems manifestly impossible to institute a proper routine use of the catheter. There is another class of cases where daily emptyings of the bladder are necessary and where the patients are absolutely unwilling to embark upon a catheter life, preferring to take the immediate risks of an operation rather than to incur the tiresome routine and more remote dangers of a catheter existence. Both of these classes are not only proper subjects for radical operation, but usually offer the most favorable conditions for such a procedure, as they are taken so early in the development of the obstructive symptoms; and the writer has several times enucleated obstructing prostatic masses from patients of this kind without making any previous attempt at catheter palliation.

There remains, however, a very large class of cases, many of them absolutely and obviously unfit subjects for operative measures, and all of them easily made comfortable for the time being by the routine use of the catheter. If such patients are properly supervised and cared for during the time when catheter life is being instituted, and up to the time when the urethra and bladder have acclimatized themselves to the new conditions of a catheter existence, they will often go through their lives with a sufficient degree of comfort and an ever-decreasing risk to the integrity of the bladder and kidneys. These are the cases which can properly be treated by the catheter, and so long as these conditions of comfort with steadily decreasing risk of infection pertain, the catheter remains the proper means of palliation. When for any reason these conditions are no longer possible and the catheter ceases to be an easy and efficient palliation, we reach that "certain point" where its use ends and its abuse begins. That is the moment when operative relief should be sought—then, at once—and not after months or years of exhausting struggle, to avoid an operation which was apparently unavoidable when the catheter ceased to palliate; a struggle carried on at the expense of pain, exhaustion and deterioration of the involved organs, even to an extent sufficient to materially lessen the prospects of a favorable outcome. So much for the "when."

Now let us consider with equal brevity "how" these cases shall be operated upon when the necessity for an operation has once been decided. Since Mr. Arthur McGill, of Leeds, published his cases of suprapubic prostatectomy, in 1888, the surgical world has been actively interested in prostatic surgery, and during the fifteen years just passed much progress has been made and much valuable experience accumulated. Prostatectomy, from being a slow, bloody, and inaccurate procedure carried out by the aid of cumbersome instruments, for the most part in the dark, has come to be a quick process of enuclea-

* Paper read before stated meeting of the New York Academy of Medicine, Dec. 17, 1903.

tion accurately performed under the guidance of the surgeon's visual, as well as tactile, sense. These technical improvements in the forms of operation have been marked enough to lessen materially the mortality of the procedure, and yet, surgeons have been so engrossed with the technic of the operation, and have been so satisfied with the technical advances made, that cases for operation have many times been chosen with a lamentable lack of discrimination, and we are at the present moment quite unprepared to state just how great, in properly selected cases, the real dangers of these radical operations are.

In short, it would seem to the writer that the real problem in radical prostatic surgery at this moment is the selection of the proper case, rather than the selection of this or that method of operation. Certainly few elderly men are good surgical risks and few surgeons are in the habit of performing operations of any severity upon such patients unless they be operations of real necessity rather than those of expediency. Prostatectomy no longer offers the formidable 15 to 20 per cent. mortality which it did a few years ago, but it is and must always be a serious and dangerous procedure, to be offered only to patients who are fair surgical risks, for other less serious measures for the promotion of comfort and the palliation of pain are within our reach as alternatives for the very large class of cases obviously unfit or unwilling to take an anesthetic and undergo an operation of importance. There are many prostatics whose obstructive symptoms develop at so early an age and who reach the limits of palliative treatment so early in the history of their troubles that operation becomes a necessity while they are still comparatively vigorous men in good physical condition. There are others, older men, who, in spite of advancing years, maintain the physical characteristics of those much younger than themselves. These are the cases for prostatectomy, and while it is very difficult to describe accurately just which cases come into this class, and while it is certainly impossible to take the age of the patient as the guide to such classification, the decision will be readily enough reached in any individual instance, provided the surgeon always realizes that he has another alternative for that case, if he does not quite like to assume the risks of a radical operation.

It is, then, the writer's firm belief that while prostatectomy is always the method of choice when possible, because it is the only operation which really offers a prospect of cure, and while there is a large class of patients upon whom it may properly be performed, still those cases form a comparatively small percentage of the total number demanding relief; and while the future developments of the operation will undoubtedly increase its effectiveness and will diminish its mortality, that mortality will be decreased to an even greater extent by a proper discrimination in the choice of cases for operation, a discrimination which has not pertained up to the present time. There remains, then, another large class of cases, if the writer's estimate of the conditions be a true one, who are, obviously, unfit surgical subjects and many of whom are running an unjustifiable risk merely in the taking of an anesthetic, and yet palliative treatment with the catheter is no longer possible or has never been possible for them. What is to be done for them?

It is impossible to study the experience of the last few years with the Bottini operation and its modifications without realizing that whatever may be the scope and degree of its usefulness, it is certainly a far safer procedure than the more radical operations. The writer has been for years very skeptical as to its usefulness and occupied the very irrational position of those who, while having no personal experience with the operation, still condemned and did not use it. The following case compelled an interest in the operation which further experience has developed into the conviction that it has a wide field of usefulness. The patient in question was under ether anesthesia for a prostatectomy which was to be carried out in the hope of relieving a condition which had resisted all efforts at palliation. The man was an unfit surgical risk and, shortly after full etherization was attained, collapsed, and the operation had to be discontinued. A few weeks later, under local anesthesia with four per cent. cocaine and with the Bottini instrument as modified by Young, of Baltimore, three incisions were made. There was practically no period of convalescence, and in forty-eight hours the man was passing his urine sufficiently for his own comfort. He is now, a year or more later, doing his day's work, using no catheter, and his bladder contains only a few drams of residual urine.

Further experience with the operation has increased the writer's belief in it. It must of necessity be a far less certain procedure than prostatectomy and it must always be regarded as a palliative measure resorted to in cases where the more radical operation is not safe; but with every recognition of the limitations of the use of the cystoscope in such cases it seems to me that cystoscopic and other instrumental examination will usually give the operator a sufficiently accurate idea of the conditions, to make the operation anything but the "step in the dark," which so many surgeons choose to characterize it. I also believe that the interchangeable knives of the instrument, as modified by Young, make the operation safer, as well as more accurate. My idea of the operation, then, is that it is attended with little risk to life because it needs no general anesthetic and because it has so short a period of convalescence; and, while its results are less certain than those of prostatectomy, they offer the patient a prospect of such a degree of improvement as shall at least do away with any further necessity for the systematic use of the catheter, and to give the operation a large field of usefulness in cases where prostatectomy cannot be safely carried out. I also believe that these cases

form a far larger class than those suitable for prostatectomy.

The writer is quite aware that these remarks are merely statements of his own personal experience and convictions and they must be so taken. If they meet with favor, they may at least serve to coordinate and arrange the ideas of other writers. If they do not represent the beliefs of others, they will serve all the better to promote the discussion, which is the object of this meeting. The points which these remarks desire to emphasize are:

(1) That the catheter has as wide a range of usefulness as it ever had, in the palliation of obstructing prostatic hypertrophy.

(2) That the various operative procedures at present at our command are to be resorted to, with the exception of certain small classes of cases referred to in these remarks, after the catheter has ceased to palliate.

(3) That the time for this operative interference is at the moment when the catheter has ceased to palliate and not after months or years of further and unavailing struggle to make it do so.

(4) That the more radical operation of enucleation, on the one hand, and the Bottini operation with its various modifications on the other, are not procedures of the same kind, do not have the same object in view, and are in no sense to be weighed in the balance, the one class against the other. They should rather be contrasted, the one class as radical operations aiming at a cure, and the other as efficient palliating procedures, each having its own distinct indications for its appropriate use.

REFLECTIONS ON THE SURGERY OF PROSTATIC HYPERTROPHY.

BY JOHN G. SHELDON, M.D.,
OF TELLURIDE, COLORADO.

In this paper, I shall simply describe the methods that I now employ in the treatment of patients suffering from hypertrophy of the prostate gland and its sequlæ. I shall not discuss the various operative procedures that have been recommended for the relief of prostatic hypertrophy; neither shall I consider the advice given by various authorities or the many theories and operative procedures elaborated by them. My excuse for giving my personal experiences to the profession—when that experience is so limited—is that the great majority of the recent original articles, although full of advice and methods, are practically without the relation of actual experiences and the detailed reports of cases. I should be pleased to see a report, from several of our representative surgeons, stating briefly the condition of the patients when they applied for treatment, what was done for them, and the result obtained.

I am of the opinion that infection is the all-important consideration in the treatment of prostatic hypertrophy. A man will, in many instances, suffer the difficulties that he experiences in urinating and the calls to urinate at night, without complaint; and he will usually obtain prompt relief, through the services of his family physician, from complete retention; but when his urinary tract becomes infected, as it usually does sooner or later, he considers his illness seriously and demands relief from his suffering. In my experience, the history of these patients is as follows: They consult a physician, for the first time, when symptoms of complete retention are present. These are relieved usually in one of three ways: Sometimes a sitzbath and hot applications are sufficient, the catheter may be successful, or a suprapubic puncture may be necessary. No matter which method is used, the patient often experiences relief for some time, provided infection does not occur. The marked improvement that sometimes follows when patients have been subjected to suprapubic puncture has been studied by E. Goldman (*Beiträge zur klinischen Chirurgie*, Band xxxi, Heft 1). He believes that the adhesions resulting from the puncture elevate the bladder and diminish or obliterate the retroprostatic vesicle pouch, enabling the bladder to empty itself more completely. Working on this principle, which I believe to be mechanically correct, he has done ventrovesicofixation with some success.

When infection does occur the patient's life becomes miserable. The cystitis may be relieved by irrigation and internal medication, but usually his symptoms gradually progress in severity until he receives surgical relief or else succumbs. The only deaths of unoperated patients that I saw from prostatic hypertrophy resulted from infection and its consequences. These were two Christian Scientists who refused surgical aid.

In discussing the surgical treatment of these cases I shall divide them into two classes: (1) cases in an extreme condition, and (2) cases with sufficient vitality to withstand a radical operation. In the latter variety, I perform perineal partial prostatectomy as follows: The patient is prepared for operation and placed in the lithotomy position. A hypodermic injection of morphine and atropine is given one-half hour before the patient is anesthetized. After he is asleep, a grooved staff is inserted into the bladder. A median incision, about one and one-half inches long, is made in the perineum. The membranous urethra is cut and the incision carried into the prostate nearly as far as the bladder. The index finger is then inserted into the bladder as the staff is withdrawn. The interior of the bladder is explored and the prostate drawn down. If necessary, the perineal structures can be separated laterally with the index finger of the other hand. This permits the prostate to be drawn still more superficially. Subcapsular enucleation of the prostate excepting that portion lying anterior to the urethra, is then done with the index finger. A fenestrated rubber tube, one-half inch in diameter, is passed through the wound into the bladder and is fastened to the skin with a safety

pin. Gauze is packed lightly around the tube and a dressing applied. The patient is propped up in bed as soon as he has recovered from the shock of the operation; the gauze is removed at the end of thirty-six hours and the wound is not repacked. The bladder is not irrigated. The tube is removed as soon as it can be determined that the urine is nearly free from pus—from four to twelve days—depending on the severity of the infection. After the perineal wound has healed, sounds are passed into the bladder to prevent stricture.

The advantages of this method are: (1) The operation can be performed very quickly; (2) the hemorrhage and shock are slight; (3) the bladder is drained at its lowest point; (4) that portion of the prostate which displaces the bladder upward, distorts the urethra and prevents complete emptying of the bladder is removed. I shall now consider the method more in detail,—following the eleven cases that I have operated upon in this manner.

Anesthetic.—Nine of the eleven patients operated upon were anesthetized with chloroform. In two instances ether was used. In these cases there was no contraindication to the use of chloroform but, as I was not sure of the skill of the anesthetist, I felt safer in using ether. Nitrous oxide, followed by ether, would doubtless be appropriate under these circumstances, although I have not used it. In all of my cases the anesthetic was taken without difficulty and was followed by no unpleasant symptoms.

Time of Operation.—I consider that long-continued operations are not tolerated by prostatics in a weakened condition, and that the operation should be done as quickly as possible. Everything should be in readiness before the anesthetic is started. The operation, as herewith described, can be performed in less than ten minutes. If the prostate is one that requires removal by morcellation, and the patient is in bad condition, no attempt should be made to remove the prostate at the first operation. Perineal drainage will give the patient as much temporary relief as will the radical operation and the prostate can be removed later. I followed this method in one case (*vide infra*).

Insertion of the Staff.—This should not be undertaken until the patient is asleep. Great pain and discomfort are experienced by many infected patients when the staff is passed into the bladder. The time saved by introducing the staff before anesthesia is not sufficient to warrant the suffering. In only one case did I fail to pass the staff into the bladder. In this case I cut down on the partially introduced staff and then had no difficulty in getting into the bladder.

Incision.—I have found the median skin incision, one and one-half inches in length, sufficiently large to accomplish the objects of the operation quickly. The line of incision involves no structures of importance and affords better drainage than does a transverse incision.

Senn says (*Journal of the American Medical Association*, August 15, 1903) "the median incision so much praised by some surgeons is altogether inadequate in difficult cases." Van Hook says "the incision need not be longer than one inch or one inch and one-quarter. The writer has frequently removed a very large prostate through an incision less than one inch long."

The longitudinal division of the centrum tendinum perineum has the following advantages: It removes the support of the prostate, allowing it to be drawn down into the wound. When the operation is completed, the weakening or loss of perineal support assists in depressing the elevated portion of the bladder, it obliterates more completely the retroprostatic pouch, and assists in completely draining the bladder. Goldman recognized that when the bladder was elevated the retroprostatic pouch was obliterated and the bladder enabled to empty itself. His operation of ventrovesicofixation is based on this principle. E. W. Andrews (*Journal of the American Medical Association*, October 18, 1902) accomplishes the same result by freeing the prostate anteriorly and allowing it to sink into the perineum. Hawley (*Annals of Surgery*, November, 1903) advises removal of the perineal support of the prostate, with drawing down of the organ in order to obliterate the retroprostatic pouch and allow the bladder to completely empty itself. Zuckerkandl avoids the loss of perineal support by dividing the centrum tendinum of the perineum transversely. Van Hook follows his advice. I have seen no unpleasant results following loss of support of the perineum in these operations.

Incision of the prostate in the median line has been done by Jones, of Rochester. I believe that its advantages are these: It easily allows the finger to pass into the bladder, and makes an opening into the capsule of the prostate in a place that is practically free from blood vessels.

Exploring the bladder with the index finger is readily and quickly done. On two occasions I removed stones from the bladder. After the bladder has been explored, the finger should be hooked over the prostate and the organ drawn down. In two cases I separated the perineal structures. This allows the prostate to be drawn down more easily. I have had no experience with instruments devised to bring the prostate into the wound. The finger has served me well for this purpose.

Enucleation of the Prostate.—The prostate is removed with the index finger assisted by a bullet forceps or a volsellum, if necessary. The finger is introduced under the capsule of the gland through the median prostatic incision. The capsule of the gland is sufficiently torn with the finger to allow removal of the lobes. I usually remove the prostate in three separate pieces. In one case I incised the capsule of the prostate. It was so resistant that I feared injury to other structures while tearing the capsule. I have had two cases in which it was necessary to remove the prostate by morcellation. In these cases it can be taken out with a cutting forceps, like those advised by

Guyon, or curved scissors can be utilized for this purpose. If it is found that a prostate must be removed by morcellation, and the patient is in poor condition, a tube should be placed in the bladder and the prostate removed later. This I did in one case.

I do not irrigate the bladder in these cases. I am of the opinion that an infected wound or cavity will heal satisfactorily if efficient drainage, in the most dependent part, is provided for; and that irrigation is not only contraindicated, but is harmful under these circumstances.

It is my custom to saturate the gauze that is packed around the tube with compound tincture of benzoin. I imagine that by so doing a film is formed over the exposed tissue that prevents the absorption of urine and septic material. Of course the gauze thus prepared does not drain. This is no objection, as in these cases we wish to drain only the bladder and want to protect the operation wound from infection.

Hemorrhage has caused me very little trouble in doing these operations. The median incision, rapid operating, subcapsular enucleation and quick packing reduce the loss of blood to a minimum.

In three instances the patients suffered from temporary incontinence of urine after they had recovered from the operation. In these cases the incontinence ceased without treatment in three, five, and seven weeks, respectively. The same condition occurred in two of Van Hook's cases. One was relieved by faradism; and in the other the dribbling ceased without treatment. In my cases, the patients urinated normally for about one week. Then the dribbling continued for from three to seven weeks after which time the patients urinated normally. The explanation of this might be as follows: The granulation tissue, distal to the bladder, would not be resistant enough during the early stages of healing to prevent closure of the canal after urinating. Later, the granulation tissue would become so firm as to prevent complete closure of the canal and dribbling result. As the healing became more complete, the new tissue would become pliable and allow complete closure of the canal.

I have had no case followed by stricture, but have passed sounds to prevent this complication. In one case a right-sided epididymitis complicated convalescence. It gradually subsided and gave no further trouble.

My experience with prostatectomy is limited to 17 cases: Four suprapubic prostatectomies—three deaths, one good result. Two cases operated by the combined suprapubic and perineal method—one death and one good result. Eleven operated by the method herewith described, good results following each case.

My first case was done by the suprapubic method. The result was satisfactory. The next two cases were done by this method and both died. I then performed an operation by the combined method and got a good result. The second case, operated in this manner, died. I then had an experience that meant very much to me:

While in a small town in Iowa I was asked to witness an operation for stricture of the urethra. The operator told me that he was going to do an external urethrotomy and asked me to look the patient over with special reference to his heart. The patient was fifty-six years old and gave the history of a prostatic with infection. Rectal examination, showed the prostate markedly enlarged. When the patient was asleep a grooved staff was inserted into the bladder and cut down upon. Then a rubber tube was placed through the perineal wound into the bladder.

Six months later this same patient came to me and said: "I was well for two months after the operation. Since that time, I feel that my old symptoms are returning." His bladder was slightly infected at this time. I did a suprapubic prostatectomy and the patient died four days after the operation was performed. At this time I decided that if I ever operated on another prostate gland I should provide perineal drainage of the bladder; and if the patient's condition warranted it, I should postpone the removal of the prostate until his general condition had improved. The operator, whom I watched, violated all rules of diagnosis, pathology and surgery, but succeeded in relieving the patient temporarily; my treatment met the pathologic condition, but the patient could not stand it. The two cases that I have operated upon since the foregoing experience are as follows:

Case I.—The patient was seventy-eight years old; was infected and in very poor condition. I decided to simply do a perineal drainage of the bladder. The perineal cystotomy was accomplished so quickly and the patient was standing the anesthetic so well that I decided to attempt removal of the prostate through the incision. I succeeded in enucleating the prostate quickly and easily. The patient made a rapid and uneventful recovery. I have had eight other cases that correspond to this one. The complications and accidental happenings that occurred have been discussed in the foregoing.

The two cases, that required morcellation of the prostate, are as follows: One case was done while I was away from home, on a hunting trip, and I did not have my surgical instruments with me. An ordinary sound was used to replace the grooved staff and the operation proceeded in the ordinary way, until it was found that the prostate must be removed by morcellation. This was done by using curved scissors, artery forceps and a sharp curette. The second case requiring morcellation was in very poor condition. When it was learned that the prostate could not be removed in the ordinary way, its removal was postponed on account of the weakened condition of the patient. A tube was inserted into the bladder. Three weeks later, the prostate was removed by using the finger, bullet forceps and scissors and a Löwenberg adenoid forceps. The operation con-

sumed little time and the patient made a good recovery. I have since had a cutting forceps made, on the principal of the Guyon instrument, but have not had an opportunity to use it.

Conclusions.—(1) Infection is the all-important consideration in prostatics; (2) perineal drainage of the bladder relieves the patient; (3) many of these patients will not stand extensive operative procedures or long continued anesthesia; (4) partial removal of the prostate, by the method herewith advised, will be tolerated by many infected patients, and a good result obtained; (5) perineal drainage of the bladder only should be done in desperate cases and in debilitated patients in whom morcellation is necessary. In these cases, the prostate should be removed at the second operation.

MEDICAL PROGRESS.

MEDICINE.

Cholelithiasis and Cholecystitis.—These conditions are most often observed in stout, constipated, inactive women of middle age or older, predisposing factors being indolence, gluttony and constipation, writes C. G. Stockton (Buffalo Med. Jour., April, 1904). The cholecystitis of typhoid fever is the type of freshly developed, uncomplicated infection. Yet even here soft gall-stones containing living typhoid bacilli may be found. In chronic typhoid cases calculi are regularly present. So, given a perversion of the nutrition of, and exudation from, the lining membrane of the gall-bladder, and calculi may be expected. In acute cholecystitis the cystic duct swells and is closed off, the lining membrane pours out an inflammatory exudate and the gall-bladder swells. It may thus project below the liver and may be palpated. The right lobe of the liver is usually enlarged and there may be pericholecystitis with adhesions. Pain may be absent, but there is usually continuous suffering, with paroxysms like colic. There may be fever with chills and sweating, and as a rule there is vomiting, with often constipation and moderate tympanites and jaundice. A leucocytosis even up to 30,000, may be expected, whether the inflammation is suppurative or not. Numerous small soft calculi may be passed during the intervals of improvement. In many subacute cases the pain and tenderness, fever and digestive derangement markedly subside, but the large, elastic rounded tumor is felt below the liver-edge, and may be accompanied by a tongue-like projection of the liver. If the case is protracted, the gall-bladder may become thickened, and retracted so that it cannot be felt, and it may be adherent to liver, omentum, intestine, or pylorus, in each case producing important symptoms or vague disturbances of the stomach and bowels. Patients may go for years without any symptoms sufficiently well marked to clear up the diagnosis, yet always in poor health. They may be treated for stomach symptoms or intestinal symptoms, or from time to time may have gastralgia not at all resembling biliary colic. The most common form, however, is that with recurring biliary colic, and it may be confused with stone in the common duct, or obstruction from cancer of the head of the pancreas. With stone in the common duct the gall-bladder is usually contracted. The colic may occur even when the stone is quite too large to engage in the cystic duct. When in the course of cholelithiasis a severe and continuous pain develops, with swelling and rigidity in the region of the gall-bladder, with great tenderness, fever, vomiting and retching, and usually considerable tympanites, we have reason to suspect pericholecystitis. In such cases the danger of perforation should always be borne in mind. As to treatment, an operation is not imperative as soon as a diagnosis of gall-stone has been made, but, on the contrary, many will completely recover by medical means alone. Patients should eat simply, drink freely of water, keep the skin active, exercise moderately, avoid excesses, and keep the bowels free; in other words, prevent a lithemic or acid condition. In irritative conditions olive oil in teaspoonful dose every two hours for several days, or salol, sodium salicylate or antipyrin may suffice. For acute attacks, morphine and atropine will be necessary.

Pancreatic Cysts and Stones.—In a second, very comprehensive article, P. Lazarus (Zeitsch. f. klin. Med., Vol. 51, Nos. 5 and 6 and Vol. 52, Nos. 1 and 2) discusses prognosis and treatment of pancreatic cysts and stones. The former if situated in the head are accompanied by more serious disturbance than in the tail. The prognosis is here rendered grave by the loss of pancreatic juice, the gastric and intestinal disturbances, interference with circulation, severe colics and diabetes. A spontaneous cure is certainly the exception; as a rule the cyst soon refills. Less frequent accidents are hemorrhage, suppuration, ileus and intestinal perforation. Of the three possible surgical procedures, puncture should be avoided. Cystectomy is the ideal method but often the deep position of the growth will only permit incision and drainage by means of anterior or posterior pancreotomy at one or two sittings. The cyst-contents are generally sterile so that there is little danger of infection. Sometimes as much as 500 to 600 c.c. of fluid will discharge in twenty-four hours and the neighborhood of the fistula will often become eczematous owing to the digestive action of the fluid. Another interesting disease of the pancreas is stone-formation which seems to have the same causes as cholelithiasis. Retention is very likely to occur within the ducts since the pancreas lacks the muscular tissue of the gall-bladder and is not in such direct proximity to the diaphragm; though a second duct is present this is generally also implicated in the inflammation. The experimental ligation of large or small portions of the pancreas, never leads to stone-formation since the stagnant juice is rapidly absorbed; a simple infection also gives negative results but if the author combined both, stone eventually formed in cystic dilatations. A precipitation of lime salts from pancreatic juice can only be induced by decomposition and by disintegration of epithelial cells secondary to catarrh; these cells and bacteria form the nucleus of the stone which soon becomes encrusted with lime. Rarely stones may also form secondary to necrosis or indurations of arteriosclerotic, alcoholic or luetic origin or after chronic interstitial inflammation. Anatomically a stricture, obstruction or compression of the duct is generally found while the pancreas is the seat of an interstitial process, not rarely with lipomatoses and fat-necrosis. The organic constituents occurring in stones are epithelial cells, leucocytes, crystals of fatty acids and detritus, the inorganic chiefly carbonate and phosphate of lime. The bacteria present are generally colon bacilli or streptococci. The most usual location of stones is the chief duct near the orifice, where they may compress the choledochus, though gall-stones more often compress the pancreatic duct. They occur in all sizes, are frequently multiple and brittle and less often faceted. The most feared complication undoubtedly is suppuration, since it may lead to bursal empyema or perforation into a large vessel with sepsis. It is a strange fact that the relation between stone and cancer is not so intimate as in the case of the gall-bladder, thus cancer is probably the most common disease of the pancreas while stones are rare.

The etiology of stones often points to a simple gastroduodenitis, but a catarrhal sialangitis may also result from intestinal infections such as typhoid or dysentery, from malaria or from septic and pyemic conditions while an indurative pancreatitis may have arteriosclerosis, lues or alcoholism for its cause. A hereditary tendency probably does not exist and males are affected five times more often than females. An idea of the frequency can only be obtained by post-mortem examinations and the only available statistics gives 1.64 per cent., while for gall-stones the figures are 5 to 12 per cent. The symptomatology presents many puzzling features; often large stones are found at autopsy which have given no symptoms while smaller ones may cause excruciating suffering. The close proximity of the organ to many important structures explains the great variety of symptoms occasionally encountered; those dependent upon the pancreas itself are colic, discharge of a calculus per anum, diabetes and cachexia. The colicky attack is often preceded by digestive disturbances; it is localized under the left costal margin and may spread to the vertebral column and left shoulder-blade. The onset is often marked by a severe chill and followed by reflex salivation and vomiting. Disturbances of circulation such as cardiac weakness and collapse occur here like with other severe abdominal pain. The temperature is never very high; sometimes there is jaundice with swelling and tenderness of the liver and gall-bladder and after the attack a peculiar feeling of hunger and thirst may be complained of. Locally the tenderness is seated in the epigastrium or left hypochondrium, depending upon the position of the stone. It is of the utmost importance to search the stool for stones but considerable patience is required since they may not appear for days or weeks and their absence does not argue against the diagnosis since they are often comminuted in the intestines owing to their brittleness. Diabetes is a frequent symptom of stone, but does not depend on this but upon the secondary chronic inflammation and destruction of gland tissue. Strangely enough the islands of Langerhans which are now regarded as forming a separate ductless gland analogous to the thyroid and hypophysis, seem to be peculiarly resistant toward invasion by fibrous tissues; they may be in every way normal in glands almost completely changed into connective tissue. Their relation to true diabetes has not been definitely settled; they are occasionally present, occasionally absent in this disease and the same is true for the indurative pancreatitis after stone. The character of the glycosuria varies: it may run an acute or a chronic course or may be intermittent with every colic; suppuration seems to exert a favorable influence. The urine is often poor in indican and in the absence of jaundice, the presence of a large amount of fat and of striated muscle fibers form a valuable guide. The cachexia is ascribed to the diabetes and to disturbances of assimilation. Rare symptoms are dyspepsia owing to adhesions with stomach and intestines, bronzing of the skin due to compression of the solar ganglion and aneurism of the descending aorta; infrequent complications are acute pancreatitis manifesting itself by fever, tenderness and continuous pain over the organ; hemorrhage, necrosis, suppuration and carcinoma.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

A Possible New Form of Mediterranean Fever.—The clinician, like the rest of human beings, is often too ready to follow the lead of others. Patrick Manson (Brit. Med. Jour., March 5, 1904) calls attention to the length of time which elapsed from the discovery of the plasmodium of malaria to the dawn of a knowledge that there was such a thing as Malta fever, a separate and distinct type of disease. He presents the photograph of a spirillum which he isolated from a woman who during her residence of three years in Gibraltar, had enjoyed good health. She was bitten on the cheek, presumably by a mosquito, and the wound behaved very unkindly. Three weeks from the time she was bitten she had a rigor, followed by a temperature of 104° F. After profuse sweating the fever terminated four days later. Ten days later there was a recurrence of the fever which lasted three days, rising again to 104° F. One week later she had a similar attack. In all there were five recurrences. The attacks gradually diminished in severity. In the intervals she was quite well. Two months after the first attack, she miscarried. Morphologically the spirillum differed from *Spirillum Obermeieri* in that the curves, instead of being short and abrupt flexures, were few and graceful. It is by no means out of the realm of the possible, in the opinion of the author, that this may be one of a number of different forms of malarial fever of which Malta fever is at present the only one generally recognized.

Anatomical Characteristics of Filaria Perstans.—The distribution of this parasite in East Equatorial Africa is said to correspond almost exactly with the area distribution of the banana and of clothed people. Low states that in the virgin forests of British Guiana, in areas where there are no bananas, it exists in 50 per cent. of the aboriginal Indians. H. C. Bastian (Lancet, March 5, 1904) discusses the problem as to whether it is necessary for the parasite to have an intermediate host or not; as to the anatomy of the worm and the question of the genus to which it belongs. He enforces the following points: (1) We know next to nothing concerning the internal anatomy of *Filaria perstans* and are therefore quite unable to say to what genus it belongs. (2) It is erroneous to say that nematodes pass through one or more metamorphoses, as they probably attain maturity by a process of steady and progressive development. (3) Nematodes stand in no need of being harbored by intermediate hosts but are from the earliest moment capable of maintaining an independent existence. (4) As a consequence, plants or vegetables, as well as water, are probably the sources through which nematodes enter the human body.

Presence of Albumin in the Feces.—Albumin does not occur normally in healthy feces, even when much albuminous food is ingested, but after about fifty grams of somatose traces of albumose and peptone can usually be detected. A. Albu and A. Calvo (Zeitsch. f. klin. Med., Vol. 52, Nos. 1 and 2) examined the stools in a number of intestinal and other diseases for albumose and peptone, including typhoid, with negative results. Despite undoubted lesions in the intestinal walls, the remaining normal mucous membrane is able to assimilate all albumin. Unaltered albumin, however, was found in 20 per cent. of the gastro-intestinal cases and in these traces of albumose occurs after large doses of somatose. In nurslings all these substances are found more constantly, even in health. It is possible that in many cases the albumin does not come from the food but from the leucocytes and epithelial cells of the mucosa.

Condition of the Kidneys in Gastro-enteritis of Nurslings.—It was rather a revelation to M. Hohlfeld (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) to find very distinct evidences of parenchymatous nephritis in all cases of gastro-enteritis and cholera infantum in nurslings which came to autopsy. The kidneys seem to be very sensitive to all intestinal changes, but since the lesions resemble those of intoxications and infections, the etiology is probably the same, since intestinal decomposition products and bacterial toxins

circulate freely in the blood. The bacteria themselves play no part, as they could only rarely be found in the renal tissues and then were not surrounded by reactive inflammation, so that their invasion must be looked upon as agonal or post-mortal. Bacterial infarcts are very rare. In the more chronic intestinal disorders the nephritis is more interstitial in type since an active proliferation of the perivascular connective tissue goes on. Clinically, hydrops and edema are infrequent and moderate, the urine generally contains a small amount of albumin, few white and red cells and more abundant renal cells, hyaline, granular and epithelial casts. The sudden appearance of hematuria argues more for hemorrhagic infarct than for hemorrhagic nephritis. The lesions are least marked in chronic gastro-enteritis and most intense in acute colitis. A thrombosis of the renal vein can only be diagnosed if anuria sets in. The prognosis in general is good if an interstitial process has not yet set in. Therapeutically, subcutaneous saline infusions are particularly recommended.

Bacteriological Examination of Blood After Death.—Before it was customary to make blood-cultures during life, the blood was frequently examined bacteriologically after death, but owing to imperfect technic, very unsatisfactory results were obtained, as many of the findings could only be explained by an agonal or post-mortal invasion of bacteria. If the blood is taken from the heart instead of the peripheral veins the cultures will be less frequently sterile in septic diseases since the temperature does not fall so rapidly after death and an active proliferation of bacteria continues, for some time. M. Simmonds (Virchow's Archiv, Vol. 175, No. 3) has had experience with 1,200 cases and finds the results very reliable. He proceeds as follows: Not later than thirty-six to forty hours after death, the right ventricle is singed with a hot knife and a sterile syringe then introduced. One to twenty drops of the aspirated blood are diluted with a tube full of fluid agar and then plated in the usual way. After twenty-four hours a diagnosis is generally possible, especially since the growth of many germs is characteristic on blood-agar, thus colonies of streptococci can be recognized by their light areola induced by hemolysis, those of pneumococci generally possess a greenish color, while the colonies of colon bacilli are large and tend to spread superficially after they have reached the surface. The findings agreed remarkably with those obtained during life and evidences of a post-mortal invasion could hardly ever be obtained. In almost half of the cases, the blood was found infected and the germs commonly present were streptococci. In about 95 per cent. of the cases only one variety of germ was present, but frequently the plates were so overcrowded with colonies that other forms might have been overlooked. Typhoid and anthrax bacilli occurred only with their respective diseases, pneumococci in croupous pneumonia, exudative pleurisy, meningitis and tuberculosis, and rarely in malignant endocarditis, acute osteomyelitis and suppurative peritonitis; staphylococci in osteomyelitis, pyemia and septicemia, streptococci chiefly in scarlet, diphtheria, phthisis and infections; colon bacilli in diseases of the abdominal organs. From one case of malignant endocarditis, a growth of diphtheria bacilli was obtained. The blood was sterile in acute tuberculosis, polyarthritis, chronic diseases of the heart and arteries and of the nervous system, chronic bronchitis and emphysema and in the newly born. The largest number of bacteria were found with streptococcus, less in coli invasion and very few when pneumococci and typhoid bacilli were present; in the latter case better results were obtained with blood taken directly from the spleen. In 129 cases of scarlet fever the blood was sterile only 39 times; these patients died during the first three or four days of the disease before necrosis of the pharyngeal mucous membrane had developed. With streptococci there was always a severe tonsillitis, pharyngitis or rhinitis or some suppurative process. In 68 cases of diphtheria, streptococci occurred 38 times, pneumococci once; here also a pathological process in the nasopharynx could usually be detected. For measles the figures are: sterile ten times, streptococci four times, pneumococci once; for phthisis, streptococci 28 times, pneumococci four times, colon bacilli five times, sterile 66 times. Statistics for tubercle bacilli could not be obtained on account of the long time necessary for their growth. It seems clear that mixed infection plays a very prominent rôle in active consumption and ready portals of entry for streptococci are found in the pulmonary lesions and for colon bacilli in the intestinal ulcerations. In cases of pyemia, staphylococci were the usual findings and it seems that these germs more frequently set up embolic and metastatic foci than streptococci—an observation which has also been made during life. Rarely a case of decided sepsis will give only sterile cultures, both before and after death, and it is possible that some anaerobic bacillus was the cause or that the condition was merely an intoxication. Positive cultures with malignant tumors could generally be explained by the breaking down of the tumor and the germ found always corresponded to the situation of the growth. In one case of operated uterine cancer, no breaking-down was found, so that infection during operation and rapid multiplication in the blood-stream must be held accountable. This is probably of frequent occurrence after operations and catheter-fever is most likely also due to blood-infection, but as a rule the germs are excreted equally as rapid. Especially interesting results were obtained in peritonitis. Though the peritoneum forms a large surface with great powers of absorption, sterile cultures were common even where putrid fluid was found in the abdomen, but when the patient had been operated, colon bacilli and streptococci were frequent. The great value of post-mortem blood examinations is evident from the fact, that frequently the cause of death could not be cleared up at autopsy until the presence of streptococci, etc., gave evidence of a sepsis.

Origin of Plasma Cells.—The connective tissue of the skin is extremely rich in cellular elements which vary considerably under different conditions. In health the spindle-shaped cells are poor in protoplasm and contain a small nucleus with little chromatin but in chronic infectious processes a marked hypertrophy and hyperplasia of the cellular elements is seen. It is here that plasma cells abound and these can be described best with L. Ehrlich (Virchow's Archiv, Vol. 175, No. 2) as hypertrophied connective tissue cells of more rounded form and more granular protoplasm. Tumefactions consisting chiefly of plasma cells, may be termed plasmomata; these include most of the chronic infectious granulomata and the lesions of a variety of skin diseases. By means of special stains the plasma-cell can now be clearly differentiated from all other elements and then appear as round cells when fully developed, more or less angular or elongated when compressed. Methyl green and pyronin bring out distinct granulations such as are common in pathologically degenerated cells, while polychrome methylene-blue and aniline alum give evidence of a well-marked spongioplasm which fills up the space not occupied by the granules. As a rule, one excentric or two polar nuclei are found with five to eight chromatin bodies of radial configuration and a central nucleolus. Proliferation generally takes place by direct division. In pathological states, degeneration affects the granuloplasm more than the other cell constituents, thus in

syphilis, hyaline changes begin in the neighborhood of the nucleus and gradually extend into the periphery and in edema the entire cell becomes cloudy and loses its dusty appearance. In other conditions, the distribution of the cells is characteristic, as in rhinoscleroma where they accompany the blood-vessels; in soft chancre where they lie adjacent to the superficial necrotic focus and in the hard chancre where they are everywhere permeated by connective tissue strands and in the syphilitic papule where they bear a close relation to the sweat glands. The origin of the plasma cells is traced to the connective tissue by some, to the blood by others, but the author was able to demonstrate conclusively that they are derived from hypertrophic connective tissue cells by means of a series of well-defined transitional elements.

Relation of Posterior Nerve-root to Spinal Ganglion.—According to K. Kleist (Virchow's Archiv, Vol. 175, No. 3) division of the posterior nerve-root will set up a degenerative process in the spinal ganglion which becomes less intense in a centrifugal direction and probably does not extend to the nerve itself unless some peripheral branches are severed during the operation. About one-sixth of all the cells are destroyed; they are situated in the dorsal border and the proximal pole, while the axillary zone and the ventral border remain normal but for a moderate cell-proliferation. The rarefied cells of the dorsal border will eventually be imbedded in connective tissue; the peripheral stump of the anterior root dies off, the central degenerates only partly and develops young nerve fibers. When the nerve itself is divided, the posterior root will show a degeneration which decreases in intensity toward the cord, while the ganglion loses more than one-third of its cells, especially in the axillary zone and the ventral border. Here also a connective tissue proliferation will appear. The anterior root, in distinction to the posterior, shows less marked degeneration and retains the power of regeneration. These facts prove that the majority of posterior root-fibers form an uninterrupted tract from the cord to the peripheral nerves and that the ganglion cells form an effectual barrier toward centrifugal and a less marked resistance toward centripetal degeneration.

Pathology of Scars.—The interesting article of R. Minervini (Virchow's Archiv, Vol. 175, No. 2) gives some pathological data of importance concerning the various forms of scars. In artificial wounds the degree of retraction bears a close relation to the direction of the connective tissue fibers in the skin; it is greatest when the incision is vertical to these. Within twenty four to forty-eight hours the edges are fixed in their new position by the reactive inflammation. During the period of granulation, the incision will gradually shorten but after cicatrization it will regain its former size and often elongate beyond this. As a rule, slightly shrunken scars will elongate more than those which have retracted considerably. In recent scars the epidermis is well developed microscopically and of almost normal appearance; the connective tissue is still rich in fibroblasts, blood-vessels are abundant but elastic fibers, nerves and lymphatics cannot be found. In old scars, fibrous tissue predominates and elastic fibers have made their appearance but these are few in number and very delicate and only have a lateral connection with the fibers of the surrounding skin. In wounds healed by first intention they are first seen by the end of the second month, in those by second intention by the third or fourth month, and they probably take their origin directly from cell-protoplasm and not from the fibers already present. The number of blood-vessels does not diminish with age but their caliber becomes somewhat reduced. True lymphatics are also absent during the later stages but a few delicate nerve filaments may occasionally be found. Two processes thus go on in all scars: first a change of embryonal tissue into permanent fibrous tissue, requiring one to two months and secondly, a new formation of elastic fiber and nerves, concomitant with which there is the appearance of dermal papillæ. The parts will, however, never be the same as normal skin, for glands, hair follicles and muscles are permanently absent. The functions too, are imperfect for tactile sensation is never as delicate. The histological structure of scars secondary to destructive processes and those found on the abdomen after pregnancy, resembles that of all old scars and should not be regarded as atrophic but traumatic. In atrophic scars, all the structures are imperfectly developed while in hypertrophic scars the lesions resemble those of any scar in the early stages.

Lesions after Obstruction of Salivary Duct.—In one case, where the excretory duct of the parotid gland was obstructed by a stone, O. Langemak (Virchow's Archiv, Vol. 175, No. 2) found a connective tissue hyperplasia, in a second, where the obstruction was a longer duration, there was also considerable atrophy of gland tissue. To decide if the stone acted as irritating foreign body or if the lesions merely depended on stagnation of secretion, the author ligated the duct in a number of animals, but obtained exactly the same changes in about the same time. Even when the trauma was purposely rendered more severe the hyperplasia was not more marked. It is probably caused directly by the venous hyperemia and edema which is set up by ligation.

The Blood in Pulmonary Tuberculosis.—A study of the blood in patients suffering from this disease has been made by J .M. Swan (Jour. Am. Med. Ass'n, March 12, 1904). Twenty-five cases of pulmonary tuberculosis are included and one case of extensive cavity formation due to bronchiectasis. The classification adopted is that of Grawitz, who divides the disease into three stages, the first, in which there is a beginning affection of the apex without cavity formation; a second stage in which there are symptoms of cavity formation without fever or with a slight fever; and a third stage in which hectic fever is present. The writer concludes that the blood picture in this affection is not constant. Cases were found in each of the three stages of the disease which were quite out of the limits of cellular and hemoglobin content described by Grawitz. The average case in the first stage of the disease presents a slightly reduced number of erythrocytes, a moderate reduction of the hemoglobin and about a normal number of leucocytes. In the second stage the average case presents a varying degree of leucocytosis, due to an increase in the number of polymorphonuclear neutrophile cells. The erythrocytes are present in about normal numbers, and the hemoglobin is often normal in percentage. In the third stage there is a reduction in the number of erythrocytes, a moderate leucocytosis composed of the polymorphonuclear neutrophile cells and a high hemoglobin percentage. Hemorrhage is usually followed by a marked reduction in hemoglobin, a slight reduction in the number of erythrocytes. Leucocytosis is not an invariable feature of a posthemorrhage blood. Albuminuria of itself appears to cause no constant change in the blood picture. Tuberculous diarrhea is apparently attended by a reduction of the number of the erythrocytes and of the percentage of hemoglobin and by an increase of the leucocytes. Pleurisy is usually accompanied by a polymorphonuclear neutrophile leucocytosis. There is no distinctive blood picture that will serve to differentiate between extensive cavity forma-

tion due to tuberculous degeneration and that due to other causes. Further, it was also found that leucocytosis is not a constant feature of cavity formation. The leucocytosis occurring in the course of a pulmonary tuberculosis is due to an increase of the polymorphonuclear elements and not to an increase of the lymphocytes or of the transitional cells. The absence of the eosinophile cells from the blood may be looked upon as an unfavorable prognostic sign. The increase of these cells, while the patient is under treatment, may be taken as an indication that the progress of the disease has a tendency to become arrested.

Resistance of Acid-fast Bacteria.—In a recent communication a series of experiments is presented by R. C. Rosenberger (Medicine, March, 1904), in which he has determined the actual resistance of this interesting group of bacteria to mineral acids and other reagents. He found that in doubtful cases where these bacilli are encountered, a diagnosis of tubercle bacilli can be positively made by after-treatment of the stained spread with sweet spirits if niter or glacial acetic acid, as these two reagents completely decolorize other acid-fast organisms, such as the grass and butter bacilli and the smegma bacillus. The author claims that inoculation experiments should always be made where only a few organisms are observed.

Adenoma of Sweat Glands.—There is no question that the sweat glands of the skin sometimes undergo adenomatous hyperplasia, though many of the tumors reported in literature are not true adenomata. L. Pick (Virchow's Archiv, Vol. 175, No. 2) has carefully reviewed the subject and finds that beside the intimate relation of these tumors to the glands, there are certain well-defined morphological characteristics. These are a double layer of epithelial lining, simulating that of the excretory ducts, an elastic limiting membrane surrounding the ducts and a lumen filled with excretory products. Three varieties of tumors may be distinguished: Those derived from fully developed glands, those taking their origin from the epidermis or from rudimentary glands, and lastly, mixed types. Occasionally the excretory duct alone is involved (syringo-adenoma) but an undoubted adenoma of the coil alone (spiradenoma) has not yet been described. Upon the vulva, these tumors closely resemble adenocarcinoma. Among other tumors may be mentioned benign epithelial growths and carcinomata which may retain their specific character or closely simulate epitheliomata of the skin.

EYE, EAR, NOSE AND THROAT.

Pulsating Exophthalmos.—The majority of the cases of this distressing condition result from an arteriovenous aneurism of the carotid artery and cavernous sinus. A few are undoubtedly due to spontaneous aneurism of the ophthalmic artery; 71 per cent. of cases follow traumatism. F. W. Murray (Ann. of Surg., March, 1904) states that immediately following rupture of the artery, blood escapes into the sinus. The increased pressure interferes with the venous pressure through the superior ophthalmic vein and passive congestion results. The symptoms of this may develop rapidly or slowly, depending upon the opening between the artery and sinus. Characteristic symptoms are exophthalmos, pulsating tumor at the inner angle of the orbit and bruit. The protrusion of the eyeball is in most cases extreme. The lids swell, and become edematous. The conjunctiva is chemotic. Its veins are distended and tortuous. Its circulation is reversed. The vein becomes practically an artery and forms a pulsating tumor above and to the inner side. Sight may be unimpaired, but it grows weaker and blindness will follow unless the lesion be removed. Subjective symptoms are marked; headache and other cerebral disturbances being the usual cause for the patient's seeking relief. Compression of the carotid affords temporary relief of the symptoms. Ultimately, unless treated, these cases all go on to a loss of sight, with the exception which proves the rule, of a few which have gone on to spontaneous cure. The therapeutic measures are limited by the morphology of the parts to a simple reduction of pressure in the sinus so that passive congestion of the superior ophthalmic vein may be relieved. Ligation is the operation of choice and in six weeks at the outside, cure, in successful cases, is complete by this method. It is interesting to note that the general mortality after ligation of the common carotid is probably about 25 per cent. In such ligation, however, in the case of exophthalmic patients, the mortality is not over 10 per cent. Reference to the tables of Sattler and Slomann shows that the percentage of cures were in each case about 50 per cent., the mortality being about 4 per cent. Blindness may result if the operation be done too late. In the tables referred to, the time of its inception was from four to sixteen weeks. Recurrence is more frequent in the traumatic cases. Those patients who are blessed with a low grade of compensatory circulation have the highest chance for recovery. The superior thyroid artery plays an important part in this circulation, and in several cases, it was found, some weeks after the carotid ligation, to be dilated and strongly pulsating. This suggests the desirability of tying the external carotid below the origin of the superior thyroid. This delays the establishment of a collateral circulation. It may occasionally happen that both common carotids have to be tied for the cure of pulsating exophthalmos. There are six cases in all recorded, an interesting observation on them being that they were accomplished without mortality and in five cases there was either marked improvement or cure. In conclusion, the author stated that in his opinion the internal carotid should first be tied, this failing, the ligation and resection of the branches of the superior ophthalmic vein at the inner angle of the orbit should be done, and if necessary a resection of a portion of the main vein. In case of this failing, ligation of the opposite carotid should be instituted.

Serum Treatment of Hay Fever.—The claims made by Dunbar for the efficacy of this plan of treatment has led a number of other observers to report their results. A series of ten cases is published by L. S. Somers (Medicine, March, 1904) who used the antitoxin made from the serum of animals inoculated with the pollen toxin of goldenrod and employed it in the form of serum and powder. One or two drops of the serum are placed in each eye and nasal chamber whenever an attack of hay fever is expected, or on the presence of any irritation. The dried serum may also be employed, when mixed with an inert powder such as milk sugar, but it can only be used in the nasal chamber. The results in these ten cases proved very gratifying. The serum produces prompt amelioration of the symptoms in the majority of cases and in a smaller number the affection may entirely disappear. Where slight or no action is seen after its use, pollen as an etiological factor does not predominate. When administered in advance of the attack or during the same irrespective of the severity, it produces marked palliation rather than absolute cure. Its effects upon future attacks is as yet unknown. The serum in powder form is slightly soothing to the mucous membranes of the nose, but has little influence upon the other symptoms and in occasional cases may act as a direct irritant.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 23, 1904.

NEW YORK'S INSANE.

The State of New York has been fortunate in the appointment of two successive Commissioners of Lunacy who have been chosen for their more than ordinary ability to organize and to administrate.

The resignation of Dr. Frederick Peterson after but two years' service would have caused consternation among those who had hoped for full fruition from the many reforms which he had started during his brief service, were it not for the fact that his successor, Dr. William Mabon, is another man of high scientific attainments and a worker for ideals.

Dr. Peterson's service has been marked chiefly by the inauguration of careful plans to make the administration of the State Hospitals more complete in scope and efficient in detail. He has endeavored to raise the State Hospitals from the level of custodial institutions to real places in which scientific study of the insane is carried on and in which active therapeutic measures are in use. This scientific idealization of the excellent custodial system of New York State has necessitated many changes which we may be able now, perhaps for the first time, to appreciate as a whole.

In addition to the establishment of 5,147 beds to increase the capacity of the present hospitals, Dr. Peterson has brought about the segregation of the tuberculous insane, by isolating them first in solariums and tents, and later in three tuberculosis hospitals which have been especially constructed for that end. Appropriations for the construction of ten isolation pavilions for infectious diseases have been secured, and he has made it a part of his policy to insist that every State Hospital shall have a separate pavilion for acute cases of insanity.

Along with this more enlightened and practical classification of the patients of the State in a broad medical way we have been gratified to observe the better means of treatment that have been provided for them, such as the installation of surgical operating rooms, hydrotherapeutic apparatus, and electrical and mechanical therapeutic aids. An improved dietary has been put in operation, with an increased ration allowance over the restricted Atwater dietary that raised such a protest. Nurses and attendants are beginning to receive better wage, making it an object for intelligent people capable of higher training to enter the service.

But apart from the betterment of the patients already under care, perhaps the most valuable work that Dr. Peterson has accomplished is the reorganization of the Pathological Institute on a thoroughly practical and common sense basis. Under Dr. Adolf Meyer original work is going on, relative to the actual needs of the insane, and during the past year a series of seminars have been held in which assistants from all over the State have participated. This thoroughly practical method cannot fail to establish a coordinate system of case examination and be instrumental in introducing some order in the purely clinical aspects of psychiatric study.

Dr. William Mabon, with his work at Willard, Ogdensburgh and Bellevue, has had the practical experience that can appreciate the far-reaching value of the changes instituted by Dr. Peterson; and it is a subject of the greatest felicitation that, having found such a man, the State has made the term of service more permanent, and has made a more adequate appropriation for his salary.

How Dr. Peterson was able to accomplish so much in two years, is hard to see, unless it were at the cost of great personal sacrifice; for the plans and problems which he hands on to his successor are such that will take many years to carry out; but if fulfilled, as we have every hope to be-

lieve they will be, the condition of the hospitals for the insane in New York City and New York State will be a source of much pride to their citizens and an example for other communities.

"HOW WE APPLES SWIM."

The desire to convert others to their own particular way of thinking, and the distribution of tracts to further that end seems to be inherent in the American breast. This missionary fad has been rampant among us, since the early days of the Colonies, when one John Tewksbury issued a screed concerning the thirty-nine articles of faith, which was more remarkable for its alliterative and alluring title of "Buttons for an Unbeliever's Britches," than it seems to have been efficacious in remodeling the stern and rock-bound religious tenets of our forefathers.

From this time the proselyting tide, reinforced with documentary arguments, ebbed and flowed. It rose with the flotsam of hydropathy, faith-cure, phrenology and other medical cults, and it fell with the jetsam of peculiar religious sects. This was probably due in part to the fact that the evangelical enthusiasts were prone to send all collected money to foreign countries for the conversion of the distant heathen, while they left the domestic article to fatten on the tracts alone, and it was also aided and abetted by that firm and unvarying support of patent medicines that seems in most cases to be donned with the clerical frock. This caused a division of interests with a stronger bias toward practice than to preaching, for it is an established fact that there is not a proprietary remedy on the market which is not endorsed by clergymen to a degree that leads to a suspicion among the ungodly that these reverent gentlemen must have led rather frisky lives in their unregenerate days if they are now obliged to take all the nostrums that they extol. It might also tend to the belief that it is only the peculiar virtues of their vaunted drugs that have prevented the curtailment of the straight coat into that of the straighter jacket.

The latest pebble that has been thrown on the beach of controversy seems to be the theory that apples are a cure for the tobacco and drink habits and are also conducive to morality. This appears to be endorsed by both Church and State, and has taken such a firm hold on the convictions of Mr. John T. Stetson, director of pomology at the World's Fair, that he announces that pamphlets setting forth the efficacy of apples, as a cure for bad habits will be distributed with 1,000,000 apples, on "apple day," September 27, at St. Louis. In order to work a cure by the apple diet, Mr. Stetson advises that when one has a craving for a smoke or a drink, that he should take an apple in its place. Just what medicinal property is contained in the fruit, the Director has the honesty to say that he does not know, but he goes on to cite Senator Cockrell's moral life, and high standard of statesmanship, as an incident of the reforming influence of apples. For he says that "it is a well-known fact that the Senator makes his own lunch of apples every day, to the exclusion of all other food, and has kept up this diet for over thirty years." This is, in itself, most interesting corroborative testimony, which, however, is hardly necessary, as it would seem that if a patient could be induced to take an apple (or anything else) every time that he "craved a smoke or a drink," in place of the tobacco or liquor, that little more would be needed.

As to apples as a food, they, in common with the whole category of acid fruits, have little nutritive value. They consist for the most part of water and carbo-hydrates, and are useful simply as a means of correction, for what has grown to be known—for the want of a better name—as "an unbalanced diet." Figuratively speaking, Americans have been charged with "eating too much corn, and too little fodder." Beefsteaks, with their proteids, have proved more tempting, and the starchy foods with their carbo-hydrates have been neglected. The result of this one-sided dietary has been a general dyspeptic feeling of *malaise*, that has not been thoroughly understood, but which has been found by experience that whisky and tobacco will anesthetize if not relieve. This has been most marked among the working classes of Great Britain, where fruit is very scarce and the prices charged for it are very high, and has, according to the London *Lancet* given rise to the belief that the man that was overfond of liquor had small taste for fruit, just as the man who cared for fruit had little liking for alcohol.

In this country, however, we have been more fortunate, if not more sensible, in the mixing of our foods as well as our drinks. Thus the apple has furnished a sauce as well for the goose as the gander, and has long been a foil for the succulent roast pig. Cranberries are always served with turkey and mint sauce has appetizingly tempered the stomach to the shorn lamb, while horseradish has added piquancy to the

rather prosaic beef. So as far as the equalization of digestion is concerned, and its indirect effect on the cravings for tobacco and stimulants Mr. Stetson and his million apples may prove a blessing to the stranger in the gates of St. Louis.

Let us hope, however, that he will not push his remedy to its full therapeutic effect,—for the result of the introduction of fruit,—particularly when immature, into the lumen of the small intestine is sometimes followed by a train of active symptoms that has been described in prose and sung in verse. We are all familiar with the poetical desire to hang Jeff Davis to a sour apple tree, with a subsequent confinement of his diet to the fruits thereof, while the little peach of emerald hue, that was the undoing of Johnny Jones and his sister Sue, is too well known to even require quotation marks. Luckily the overdose of "apple" is more painful in its effects than it is dangerous in its results, and the "balance of diet" in these cases is usually restored by the full exhibition of camphorated tincture of opium, or the free use of that domestic household treasure, Jamaica ginger. But an ounce of prevention is worth a pound of cure, and we trust that the "Pomologist's" specimens will not be "the goodly apples rotten at the core," that are usually found in country groceries, which have so many bruised sides that even the trade procuring card of "take one" fails to empty the barrel.

With regard to the influence of an apple diet on morality, we confess that we do not grasp its connection. The Reverend Lycurgus Morris, however, has discovered it, and in an address to his dusky flock has urged them to accept it, and abide with it forever. For he states "it calms the passions of men and increases the chastity and self-restraint of women, as may be shown by many instances in history, both sacred and profane." As to what particular events the Ohio parson refers, we cannot say, but he can hardly claim that Eve's period of greatest sanctity was ushered in with the eating of the fruit in the Garden of Eden, or that Helen of Troy was more circumspect in her treatment of the appreciative Paris after receiving the apple from his hands.

The colored clergy have, however, always been strong on early Biblical lore, so we hope that Brother Morris's particular orchard will be spared, like that of Uncle Remus, from the raids of ruthless marauders, either human or satanic.

"The devil thought he'd bother me
By cutting down my apple tree.
He didn't bother me at all,
For I had apples all the fall."

ULTRAMICROSCOPY.

It has long been known that by intense illumination slits in silver mirrors can be rendered visible which measure only one ten thousandth part of a millimeter in diameter. To make this possible it is essential that light rays of great intensity shall fall upon the object under examination in such manner that only the reflected rays, not those of the source of light, shall reach the eye of the observer. This principle has been utilized in the so-called ultramicroscopic examination of objects, and it has been ascertained that while with our finest microscope lenses, under ordinary conditions, the degree of linear magnification does not materially exceed the one thousandth part of a millimeter, the ultramicroscope renders possible the recognition of objects measuring but a millionth part of a millimeter in diameter. In this manner magnitudes become subject to direct inspection which lie on the border line, where the science of physics and chemistry meet in their respective conceptions of the constitution of matter. The essential point, as has just been stated, is the degree of illumination, while the actual "power" of the objectives is not increased; in other words, the size of the image is the same, but the susceptibility of the retina is increased. We see this principle exemplified in our recognition of the finest particles of dust in the atmosphere of a room when sunlight enters, and when the optical axis of the eye is at right angles to the rays of light. Under ordinary conditions the same particles of dust would remain invisible.

Ultramicroscopical examination opens up an entirely new field of research, and it is to be anticipated that medical science also will be benefited as a consequence. Bacteriological investigations especially will receive a new impetus, as the method is especially adapted to the examination of separate particles, while for the study of connected cells it is scarcely applicable.

Raehlmann has pointed out that many microorganisms can be rendered visible much more readily by the aid of the ultramicroscope than is possible by staining, examination in the hanging drop, etc., and that a great many forms become visible in this manner only. In putrefying albuminous solutions several varieties of ultramicroscopic microorganisms have been met with, which were actively motile, and in several distinct and typical alterations in form have been observed. Studies in this particular direction appear of signal value in the identification of different types.

In the secretion of trachoma Raehlmann found two ultramicroscopic types, and a markedly polymorphous organism, in which three distinct types of form could be distinguished. In the conjunctival secretion in the various affections of the eye unknown bacteria were similarly discovered.

Very interesting are Raehlmann's studies in connection with solutions of glycogen. Such solutions have a slightly opalescent bluish color and upon examination even with the most powerful immersion lenses they appear perfectly homogeneous. On ultramicroscopical examination, however, tiny little particles are seen, which in a solution of one in several thousand are so numerous that they cannot be individually recognized. On further dilution they become apparent, and it is then noted that they execute oscillatory movements which continue indefinitely. Very curiously these movements are dependent to a great extent upon the distance between the individual particles, diminishing in intensity with the degree of dilution, so that finally a point is reached where they cease altogether. Raehlmann accordingly does not regard these movements as identical with the common Brownian movements, but as the visible, motor expression of influences of gravitation, by which the particles attract and repel each other. The individual particles are apparently molecular complexes of typical structure, and may be viewed as molecules of a second order, which in their aggregate properties and relation to the surrounding water represent the typical form in which glycogen exists in solution. This supposition is borne out by the fact that on adding a few drops of a solution of a diastase to the glycogen solution it is possible to observe that as inversion goes on the particles become smaller and smaller and finally disappear altogether.

Quite analogous results have been obtained in the case of the albumins. Here also the individual particles disappear under the influence of the corresponding digestive ferments.

Noteworthy further are the results which Raehlmann obtained in a study of the aqueous humor of the eye. On ultramicroscopical examination it was found that the fluid in question contains the smallest amount of albumin of all the physiological fluids of the body. The lens, on the other hand, is very rich in albumins, which are manifestly contained in the fibers. They dissolve out when the lens is placed in water, and can be microscopically demonstrated. Under normal conditions these albuminous complexes lie firmly packed together surrounded by the elastic capsule of the lens, so that an elastic and uniformly refractive medium results. Opacities of the lens, according to Raehlmann, result not as a consequence of coagulation of the lens fibers, as has hitherto been supposed, but from optical inequalities of refraction, which are the outcome of a dissociation of the albuminous particles and the interposition of fluid. This conception of the process seems to furnish a new and satisfactory explanation of cataract formation. Quite in accord with this view is the result of the following experiment: On wounding the lens capsule with a fine Graefe lance, through the anterior chamber, the aqueous humor on ultramicroscopical examination is found filled with albuminous particles. This proves that as a result of the injury the aqueous humor does not penetrate the lens, as has been supposed, but exactly the opposite occurs, and it is assumed that these particles produce stasis in the efferent lymph vessels, and may thus be responsible for many of the concomitant symptoms of traumatic cataract, the occurrence of which has hitherto not been satisfactorily explained.

The above results are some of the few which have already been obtained with the ultramicroscope and serve to exemplify the importance of the subject.

ECHOES AND NEWS.

NEW YORK.

Chicago Meeting of Bellevue Alumni.—New York University sent as its representatives to the annual meeting of the Alumni of the University and Bellevue Hospital Medical College, held at Chicago, the present week, Dr. Joseph D. Bryant, head of the department of surgery; and Dr. Egbert LeFevre, professor of clinical medicine and corresponding secretary of the medical faculty.

Dr. Peterson and the Hospital Movement.—A recent issue of *Charities* has the following appreciative comment: "The resignation of Dr. Frederick Peterson as president and member of the New York State Commission in Lunacy, has been announced. It is greatly to be regretted that the State should lose the services of so eminent an alienist. Dr. Peterson's interest in the insane has been very largely scientific, and he has given a large share of his attention to the development and improvement of the hospital side of the State care system. The Pathological Institute in New York City, which is under the direction of the commission and which was established to pursue independent research in the field of psychiatry, and to develop, organize and correlate the scientific work of the various State hospitals, has been reorganized and strengthened, and under its capable director has been brought into relations of close cooperation with the State hospitals. Both by the courses of lectures given by the director to the State hospital physicians who have met in New York for the purpose, and by the personal visits

made by the director to the State hospitals, the medical men in the service have been much stimulated, and the scientific aspects of the care and cure of the patients have shown the beneficial effect of this influence. Dr. Peterson has also made an effort to encourage promising young men from the medical schools to enter the State hospital service as clinical assistants without salary, as is done in the case of the large general hospitals in the cities. If these young men leave the service later for private practice they take with them a very valuable experience in psychiatry, one of the most important and most neglected branches of medical science. Among the improvements which are due to Dr. Peterson's initiative is the appointment by the commission of a medical inspector, who supervises both the fourteen State hospitals and the twenty-three licensed private asylums, which were not previously, in all cases, under proper medical inspection. Another reform is the statutory provision that in emergency cases, when the condition of an alleged insane person is such that he should have immediate care and treatment, he may be received at a State hospital for five days pending the routine of procuring needed commitment papers. Dr. Peterson has advocated the most enlightened and scientific care of supposedly recoverable cases of mental disease, and has for many years sought for the establishment of separate psychopathic hospitals in the large cities for the preventive and curative treatment of insanity. Last year the bill introduced in the New York legislature to establish such a hospital in New York City failed to receive the favorable consideration it deserved, though the plan had been advocated by the Governor, and was supported by the State Commission in Lunacy, the State Charities Aid Association, and, to a large extent, by the press and the public. The similar bill already introduced this year has become law.

Hospital Appointments.—During the past week the following students at the College of Physicians and Surgeons received appointments: Hudson Street, 1st, T. H. Cherry, G. D. Hale, E. T. Hull; Alternates, R. W. Carter, C. C. Kimball. French, 1st, H. A. Craig, C. W. Walser; Alternates, G. H. Schenck, G. H. Meyer, W. Blancard. General Memorial, 1st, L. L. Miner; Alternate, H. L. Hooper. Jamaica (L. I.) Hospital, J. C. Gain. St. Michaels (Newark, N. J.), 1st, G. H. Meyer, F. H. David, M.D., P. & S., 1903. Bellevue (First Division), 1st, I. O. Woodruff, H. L. Hooper, R. W. Carter, J. D. Peters, C. G. Bandler; Alternates, J. M. Long, C. D. Cleghorn. Gouverneur, P. J. Hamill, J. D. Hastie; Alternate, E. O. J. Eytinge. Harlem Hospital, G. H. Hibler.

PHILADELPHIA.

Phipps Institute.—Dr. Randle C. Rosenberger has been appointed pathologist to the Phipps Institute for the Study, Prevention and Cure of Tuberculosis.

St. Luke's Hospital.—St. Luke's Homeopathic Hospital patients are soon to be moved from the present Broad Street building to a large house at Broad and Wingohocking streets. It is the intention to acquire the adjoining property and erect a building that will be materially larger than the one at present occupied.

Municipal Hospital.—Plans of the new Municipal Hospital now under construction show elaborate arrangements for the perfect isolation of the patients from the outside world and of those suffering from different diseases from each other. The plans include six detached buildings about 50 feet apart and connected by an 8-foot corridor semi-circular in shape, built on a radius of 400 feet. Three of these buildings will be located on either side of a central one which contains clinic rooms, laboratory, etc. On the opposite side of the corridor will be a nurses' home, a receiving room and the kitchen. Each of the units for smallpox, scarlet fever and diphtheria will have its own physicians, nurses, orderlies and ambulances. Each physician, nurse or attendant leaving the institution must each time pass through three rooms; a disrobing room, one in which antiseptic baths are taken, and a room for donning sterilized clothing. The smallpox unit is now completed.

Use of Opium Increasing.—Recent raids on opium joints in this city have led to investigations which are said to show alarming facts. It is stated that opium joints are conducted under the knowledge of the police and that the smoking of the drug has doubled within the past three years.

Sterilization of City Water Supply.—The Trades League Subcommittee on Municipal Affairs have recently urged Director Martin to sterilize chemically the water supply of the city in order to prevent typhoid fever. They recommend the use of electrozone, a disinfectant now employed on the city streets; it is made by passing an electric current through salt water. It is understood that they received no encouragement toward chemical disinfection of any kind. Officials do not speak favorably of the methods of chemical sterilization of drinking water, as recently set forth unofficially by government experts. Typhoid fever cases for the past week were 359, a slight reduction from the figures of the preceding seven days.

Tumors of the Carotid Body.—The report of a careful study of the embryology and histology of the carotid body and also of a tumor of that structure was made at the meeting of the Philadelphia Pathological Society April 14, by Dr. John Funke. The body in question was probably first mentioned by Haller in 1743. It is situated at or near the bifurcation of the common carotid artery, in size approaching that of a grain of rice. The views of different writers regarding the histology of the body are very various. Dr. Funke does not find the body present so often as is commonly stated; he found it in only one of eight fetuses. In three cats, one guinea-pig and one rabbit no such structure could be found. In one fetus a cervical ganglion occupied the usual position of the body, this fact being determined only after a careful microscopical examination. In the fetus possessing the body it was found attached to the common carotid 6 mm. below its bifurcation on one side; on the opposite side it was on the inner aspect of the external carotid five-tenths centimeter above the bifurcation. The bodies were 7 mm. in diameter and attached to the sheath of the vessel by a delicate pedicle. Histological study indicates that there is a relation between the cells making up the carotid body and the vessel itself; the writer is of the opinion that the lobules of the gland are produced by the proliferation of the endothelial cells of the blood vessel. Dr. Funke finds in the literature the reports of 13 undoubted cases of tumor of the carotid and one that is probable but not proved; to these he adds one hitherto unreported case. This patient was a male, aged forty-eight years, operated on at the Jefferson Hospital by Dr. W. Joseph Hearn. The tumor was on the right side, of six years' duration and of slow, continuous growth. To remove the tumor it was necessary to remove portions of the common, ex-

ternal and internal carotid arteries and of the jugular vein. The patient afterward developed headache, became irrational and finally died of general debility nine weeks after the operation. The tumor proved to be a perithelioma. The tumors of the carotid are usually to be regarded as malignant in nature; Reclus alone questions the propriety of operative interference.

CHICAGO.

Music for the Insane.—Music produced by a variety of automatic instruments and including airs, ranging from classic opera selections to the latest ragtime melodies, are to be tried as a curative influence on the inmates of the hospital for the insane at Dunning. Four talking and music machines, a music box and an automatic piano player have been received at the institution. The general superintendent, Dr. V. H. Podstata, believes the music will act even more beneficially on the minds of the patients. The musical instruments, which, with a supply of games, and the moving picture machine, were purchased out of a fund of $1,100 secured by donations, are later to be distributed to the various wards of the hospital and kept in use at all times. It is thought that these entertainments will act as a diversion, taking the patients' minds off their broodings and melancholy thoughts.

Land for Hospital.—Land has been bought for Chicago's great hospital for the treatment of infectious diseases, founded by Harold McCormick and his wife, who is a daughter of John D. Rockefeller. John A. Markley has sold to Mr. McCormick the one-fourth block of land at the southwest corner of South Park avenue and Fifty-third street, for $40,000, and a deal is under way for the purchase of the remainder of the block. Although no definite announcement has been made, it is believed the hospital buildings will cost $500,000, while aside from this there will be a heavy endowment. Dr. Ludwig Hektoen will doubtless be the medical director of the institution, which will be in affiliation with the University of Chicago.

The Prevention of Tuberculosis.—Dr. Arnold C. Klebs recently addressed the Hull House Woman's Club, and among other things, "sleep with your bedroom window open," was a bit of advice given by him. Continuing in his plea for fresh air, he said that the germ of tuberculosis can grow only inside an animal. Outside it can maintain existence a year but cannot grow. Warm conditions indoors are a paradise to the germ. If exposed to the sun and wind, it dies. He pronounced as a fallacy the generally accepted idea that tuberculosis is inherited, and that it may be best treated in the dry air of high altitudes. Tuberculosis can be cured just as well in Chicago as in Colorado or Arizona. Climate has no material effect upon it. High altitudes may do individual cases good. A change of scenery sometimes is advantageous. The disease is not inherited. There have not been more than twelve well authenticated cases of the inheritance of the disease in medical history. Children may be born of parents both of whom are consumptives, and not be infected. Wholesome food comes next to fresh air as a preventive. Cleanliness is another great factor. Great danger of tuberculosis infection lies in milk. Every home should Pasteurize its milk.

Fight for Pure Milk.—The expiration of milk dealers' licenses with the necessity for applying for renewals next month furnishes an opportune occasion for searching out unsanitary dairies, and for enforcing rigid compliance with the requirements of the ordinance governing the sale of milk in Chicago. The Superintendent of Milk Inspection is making preparation to take full advantage of this opportunity. In former years it has been the practice to issue licenses first and inspect afterward. A new policy is to be inaugurated. Everyone of the 3,500 dairies which furnish milk to Chicago will come under the searching eye of an inspector before the end of this month. Dealers who do not come up to the sanitary requirements of the city milk ordinances will be denied licenses. This rule is to embrace all places where milk is kept for sale or for purposes of sale to agents, whether they are actual dairies or not. To make the preventive campaign more effective, the inspectors will insist on the sterilizing of all milk bottles. This, with rigid inspection of the sources of supply and the good work of the Pasteurizing plants, should insure a high grade of milk for consumers during the coming summer.

Presidency of University of Illinois.—Dr. William A. Evans, head of the department of pathology of the College of Physicians and Surgeons, has been brought forward by a large number of the leading business and professional men of Chicago as a candidate for the Presidency of the University of Illinois. For several years he has been head of the pathological department of the University of Illinois, and is admirably equipped for performing the functions of this high office. He is in the forefront of every progressive movement, not only in the field of technical research, but in great public matters that tend to better conditions of life in every direction. Dr. Evans is backed by such men as Drs. Frank Billings, John B. Murphy, Fenton B. Turck, Victor C. Vaughan, etc., as well as by distinguished lawyers, business men, etc.

Unity of Action Sought.—Closer affiliation between the Chicago Medical Society and the dental, homeopathic and eclectic professions is the object of a Committee on Public Relations, which the Chicago Medical Society established last Wednesday evening, April 13. In urging the adoption of these amendments to the constitution which will establish this new committee, Dr. Evans stated that the dental profession had already been approached on the question of closer relations among the various branches of the healing art, and the proposition met with favor. It was essential to secure unity of action on all questions of public policy. The amendments were adopted by unanimous vote.

Mortality from Nervous Diseases.—According to the weekly bulletin of the Health Department, comparing this decade with the previous one, there is shown a decrease of 40.2 per cent. in the mortality from all forms of nervous disease, and of nearly 60 per cent. in the deaths from convulsions. Better hygiene of child life, better milk supply, better knowledge among mothers, account for this latter reduction. The Health Department remarks that it is not so obvious what has caused the reduction of more than one-fourth in the deaths of adults from nervous diseases.

Exudates and Transudates.—Dr. Joseph L. Miller read a paper on this subject at the last meeting of the Chicago Pathological Society. He said that points of difference reported between exudates and transudates are size of erythrocyte present, reaction of fluid, presence of nucleo-albumin, specific gravity and amount of albumin, and character of cells present. Size of the erythrocyte no value, as percentage of salts is the same in exudates as in transudates. Both fluids acid to phenylphthalein, exudates having

a higher degree of acidity, but not of sufficient constancy or degree to be of diagnostic value. Nucleo-albumin present in exudates; not present in transudates, but not constant, as in some pleural exudates of the writer's no nucleo-albumin was present. Variations in specific gravity chiefly due to varying amounts of albumin present, as salts show little fluctuation. Specific gravity and albumin depend upon the intensity of irritation, amount of albumin in the blood, tension of the fluid, amount of resorption, blood pressure, and possibly the presence or absence of icterus. An exudate may have a low specific gravity, due to associated anemia or cachexia, or to presence of associated transudate from local venous stasis, or associated icterus. Transudates may have high specific gravity due to associated inflammation, high tension of the fluid, presence of resorption, the salts and water disappearing more rapidly than the albumin. For these reasons, specific gravity is not a reliable index of the nature of the process. The only accurate method of determining the amount of albumin is by estimation of total nitrogen, or weighing dried albumin; bulk methods, as Esbach's or Purdy's, are extremely unreliable; much more accurate is the formula of Reuss. Percentage albumin $=\frac{3}{8}$ (sp. gr., 1,000) — 2.8. This is possible, on account of only slight fluctuation in the solids, except the albumin. Cytodiagnosis of very limited value.

Syphilis as a Cause of the Neuroses.—At a joint meeting of the Chicago Medical Society and Chicago Neurological Society, held April 13, Dr. L. Harrison Mettler read a paper on this subject. He said that the association of syphilis and functional nervous troubles had long been noted. The relationship of cause and effect between them was not so well established. On the one hand, we are not in possession of accurate knowledge as to just how the syphilitic virus affects the neurones so as to cause them to functionate abnormally; nor, on the other hand, do we know just exactly what is meant by a neurosis, its histopathology and pathogenesis. If we could solve positively these two questions the relationship of syphilis to the neuroses would be obvious. In regard to the action of the syphilis upon the neurones, the author argued that it was both direct and indirect. In the direct way it somehow disturbed the normal physiochemical activity of the neurone by a direct poisoning of its molecular contents. In the indirect way it affected the nutrition of the neurone by changing the nutritive value of the blood or limiting the blood supply by setting up disease, with all its well-known consequences, in the vascular walls. Pathologists and syphilographers were fairly well agreed that syphilis can and does thus directly affect the cellular contents, so as to disturb the functions of these cells. Moreover, the relationship of syphilis to the so-called parasyphilitic diseases, as well as its rôle in the latent form of predisposing cause to many of the organic diseases, both indicate that it can influence deleteriously the intimate structure of the nerve cells. This clears the way for the acceptance of the belief that syphilis can provoke a neurosis. All irritative and pressure symptoms caused by the inflammatory products of organic syphilitic lesions, though functional in character, the author regards as physiological rather than pathological, and omits from consideration. He adopts the view that the basis of a true neurosis is a constituent change of some sort in the nerve cells; for, as he affirms, a disturbance of function sufficient to be recognized as a disease, with the preservation of normal structure, is a logical contradiction. A neurosis, therefore, is essentially an organic disease, and is as likely to be the result of a syphilitic as of any other form of infection. In saying this, however, the author was mindful of the fact that nearly all of the earliest manifestations of the syphilitic organic diseases were functional in character for a time, hence care must be exercised in making the diagnosis, for a syphilitic neurasthenia sooner or later shows signs of a meningitis, a functional paralysis becomes an organic paralysis, or a syphilitic chorea reveals signs of Bechterew's cerebrospinal focal sclerosis. After discussing in detail syphilis in its causal relationship to neurasthenia, hysteria, the traumatic neuroses, epilepsy, migraine, chorea, functional paralyses, paralysis agitans, neuralgia, central torticollis, spasms from local ischemia, paralyses of single nerves, and various other functional and convulsive disorders, the author draws the following practical conclusions: (1) Syphilitic infection can produce a pure neurosis. Most of the neuroses so produced, however, are but the preliminary indications of gross organic syphilitic disease of the nervous system; (2) Syphilitic neuroses are as much syphilis of the central nervous system as are the organic syphilitic diseases, and they call for the same thorough antisyphilitic treatment as the latter do.

GENERAL.

Detroit Doctors at Stearns' Laboratories.—Last week the wooden anniversary of the Frederick Stearns' Biological Laboratories was held and several hundred Detroit physicians were the guests at the celebration. Open house was kept all day and there was an almost uninterrupted stream of visitors in response to the unique wooden invitations sent out a week before. All classes were represented, from gray-haired surgeons and specialists of more than national fame to young prospective graduates of 1904, including, of course, a fair proportion of ladies. The regular work of the department was carried on as usual, affording the visitors an opportunity to see in actual operation all the processes used in the production of diphtheria antitoxin, streptolytic serum and glycerinated vaccine. Perhaps nothing caught their fancy more than the modern operating rooms, rivaling those of first-class hospitals, for most physicians are great sticklers for asepsis, knowing its importance. They admired the extensive brick stables, where every provision is made for the care and comfort of 120 horses yielding life-saving serums. From this also was gained an idea of the development of the business, which five years ago was started with but three horses. There were many expressions of gratification at the abundant evidences of the care with which every step is safeguarded in the manufacture of serums and vaccine. A buffet luncheon was served in the travelers' annex, and wooden souvenirs were distributed.

Suicide.—"In an instructive article contributed to the *Independent*, Mr. George P. Upton," according to the *Times*, "perhaps the best unofficial authority in this country on the subject treated, shows that within the past thirteen years 77,617 people have committed suicide in this country. In 1902 fifty cities furnished 2,500 cases of self-destruction, out of a total of 8,132 for the entire country. Of the 77,617 suicides in the thirteen-year period, 57,317 were males and 20,400 females. The greatest ratio of increase is among young women under twenty-five years of age. Another curious fact is the increasing number of children who kill themselves. Of the methods chosen for ending life it is curious that a very large proportion select carbolic acid. It is cheap and easily accessible, no doubt, but it must cause an extremely painful death, giving the victim a brief period

of intense suffering while the vital organs are being destroyed by corrosion. The suggestion that the sale of carbolic acid should be placed under the same restraint as other deadly poisons does not seem to promise much. So many other and, for that matter, easier modes of self-destruction are available that to cut off one would probably not affect the net result appreciably. Prior to 1894 more suicides died from bullets than from all other agencies combined. Since then poison seems to have been preferred, with carbolic acid a favorite. The remainder is divided between hanging, drowning, the knife, jumping from windows or roofs, gas, fire and dynamite, while as many as 800 selected the expedient of throwing themselves in front of locomotives. · These are gruesome statistics. The lesson to be learned from them depends largely upon the point of view. For some its moral, for others its ethical, aspects predominate. For all it must mean that an increasing percentage of people of a least average sanity find life a bore, and, for one or another of an almost infinite variety of morbid and sophistical reasons, choose to end it. The more complex our civilization and the greater the opportunity for failure and disappointment, the stronger the tendency to self-destruction."

Vivisection: Two Views.—Any one who has followed up the arguments of the anti-vivisectionists during the past few years is prepared for any sort of surprise in the way of syllogisms and sophistries; and so commonly have well-meaning but misinformed members of the clergy engaged in this crusade that upon seeing an article by the Rev. Mr. So-and-So upon the subject immediately begins to draw more or less accurate deductions. A recent number of the *Outlook* contains two articles under the above caption,—one by the Rev. Wm. Lawrence, Bishop of Massachusetts; the other by Albert Leffingwell, M.D., Director of the Vivisection Reform Society. Upon giving each of these a careful reading one met with two surprises: the broad, sensible, and exceedingly tolerant view of the Bishop; and the less broad and somewhat restrictive view of the physician. The Bishop thinks that much of the agitation against vivisection is extreme because no one, even the most bigoted, hesitates to allow animals to suffer pain in procuring his daily ration of fowl, pork or beef. He says, "For the life and welfare of men animals must be sacrificed; we all accept this fact when we sit down to our Sunday roast beef." But in thinking that everybody is agreed that some vivisection is necessary he evidently is too liberal in his interpretation of facts. There are some people who even claim that they would rather be tortured themselves than see a dog have a canula thrust into his veins under the influence of an anesthetic; but of course the test is not applicable and hence the argument becomes a fairly good one on the ground of its extreme negative character. In Bishop Lawrence's experience operations on the lower animals have been skilfully and carefully done and with the least possible pain and he sees no need for the appointments of laboratory inspectors, so commonly advocated by the humanizers; for there are no secret operations and any sensible person can see what is being done for himself by tapping at the experimenter's door. Dr. Leffingwell does not condemn the practice as a whole but believes in legal regulation. His confidence in mankind is certainly not remarkable, for he thinks that "We cannot depend to-day upon our superior humanity" to make vivisection as painless as possible, and one can scarcely believe that "Some of the worst vivisections recorded in history have been made in an American laboratory within the past ten years." The reporter would be glad to know, as a matter of curiosity, where that laboratory is located; for it must surely be unique in being the chief offender, and again, not to quibble about the use of words, it would be interesting to know where to look for a history of vivisection in which his facts are recorded. But when one reads that "Brown-Séquard was one of the most cruel vivisectors that ever lived" he is inclined to cast a shadow of doubt on every statement in the entire essay. He opposes the good Bishop also, both in theory and actual fact, when he speaks of the "Veil of secrecy behind which vivisection is conducted." Such cases must be extremely few and the writer has never known a single instance where he might not have had an opportunity to visit the laboratory and study the methods employed there in detail. To restrict the practice according to the reformer's idea "Free admission should be accorded all clergymen, physicians and State legislators." Each laboratory should have a responsible director, and all experimenters should be obliged to obtain a State license. The results from each institution should be embodied in a report as to the number and kind of animals operated upon, the object of each experiment and its result to the animal. It is needless to say that this method if adopted would be cumbrous, very expensive, and quite unnecessary. In some cases it might be advisable to warn new and inexperienced operators against thoughtlessly giving pain, but an experimental laboratory is usually under the supervision of a competent investigator, who, even in his great desire for the advancement of science, would scarcely stand by and hear the outcries of an animal in pain. This might have been the case before the era of anesthetics but it is not true now. To the minds of liberal people everywhere the remedy of Bishop Lawrence against this so-called "evil" is sufficient; viz., "The great safeguard against cruelty in vivisection is the high professional spirit of doctors and investigators."

The Beverage Bill for 1903.—"Prosperity seems to lead to an increased use of stimulants," says an article in a recent issue of the *American Grocer*, and, summing up the nation's drink bill for the year ending June 30, 1903, the total retail cost of alcoholic and other stimulating beverages is estimated at $1,451,633,379. This is a considerable advance over the average annual cost for five years before, $1,293,903,358. On the basis of 80,372,000 inhabitants in the United States, the record shows an expenditure for stimulants of $18.15 for each person. The consumption has largely increased in the milder sorts, such as coffee and beer, with coffee in the lead, and while alcoholic drinks to the value of $1,242,943,118 have been taken, the non-alcoholic stimulants—coffee, tea and cocoa—amount to $200,000,000 more. Coffee is in the lead, $156,690,261 being the amount spent for it. For tea $45,000,000 was spent, and for cocoa $7,000,000. Coffee outstripped all the others, according to the following table:

	Gallons.
Coffee	1,566,902,614
Beer	1,449,879,952
Tea	450,000,000
Spirits and wines	157,130,628

One-tenth of a gallon per capita increase in the use of spirits is the largest recorded from one year to another since 1900; 148,206,875 gallons were distilled, and the consumption, including fruit and imported spirits, was 117,252,148 gallons. Of this the whisky bill is the greatest. Beer, the popular beverage next to coffee, had in 1903 the highest consumption on record; 18.04 gallons are put down to each person, a gain over 1902 of 0.55 gallons. Eliminating those who do not drink beer, it is estimated that the average person who lingers over the stein consumes from 90 to 100 gallons in a twelvemonth.

Prosperity may be the cause for the opening of more bottles of imported wines than ever and a serious falling off in the consumption from the home vineyards. The

table for the two years past is interesting by comparison and is as follows:

	Domestic. Gallons.	Imported. Gallons.
1902	44,737,244	5,017,159
1903	32,631,154	6,088,201

Leading all other nations of the world, the United States consumes nearly one million pounds of raw coffee every year. The average for the last three years has been 910,987,576 pounds.

With the exception of 1897 the imports of tea were last year the largest on record. Conservative estimates on the brewing of the 104,632,260 pounds imported place the decoction as 450,000,000 gallons, worth $45,000,000.

OBITUARY.

Sir Henry Thompson, Bart., the distinguished surgeon, died April 18. He was born in August, 1820. He is succeeded in the baronetcy by his son, Henry Francis Herbert Thompson. Sir Henry Thompson was created a baronet in 1899. He was surgeon extraordinary to the King of the Belgians, consulting surgeon to the University College Hospital, London, and Emeritus Professor of Clinical Surgeons. He was born in Framlingham, Suffolk, August 6, 1820. He was graduated in medicine at the University College, London, where he won honors. He was the author of numerous papers on scientific and surgical subjects which are generally accepted as authoritative, and also wrote two novels, "Charley Kingston's Aunt" and "All But." He was known also as a painter of ability and a deep student of astronomy.

Dr. Wilbur F. Nutten, one of the best-known medical practitioners of Western New York, is dead at his home in Newark, N. Y., aged sixty-four years. Death resulted from heart failure. Dr. Nutten was a graduate of the Medical College of Physicians and Surgeons of New York City.

CORRESPONDENCE.

MEDICAL LEGISLATION IN NEW YORK.

To the Editor of The Medical News.

Dear Sir: The legislature has adjourned, and both the Optometry Bill and the Osteopathy Bill have failed to become laws. There never was an effort made to secure legal recognition by any of these peculiar practitioners which had in it anything like the force of the Opticians' Bill of this year. In the beginning of the session the reports which I received from various quarters seemed to indicate that the measure would become a law. But thanks to the support given the Committee on Legislation by the medical profession in all parts of the State, what seemed to be defeat for us has been turned into victory. I have no doubt that the medical profession can, through its representatives, control legislation affecting the medical laws, and the public health generally. In my experience I have found the various members of the legislature not only willing but anxious to learn the views of our profession, and the majority of them are willing to be guided by our advice.

I want to thank you for the very great aid you gave our Committee, and to express the hope that sometime in the future when the necessity again arises, we may feel at liberty to call on you for the same kind of aid. Again thanking you, I am,

Very truly yours,

Frank Van Fleet,

Chairman of the Committee on Legislation, of the Medical Society of the State of New York.

SOCIETY PROCEEDINGS.

THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

Fourth Annual Meeting, held in New York City, April 1 and 2, 1904.

(Continued from Page 766.)

Case of Glioma of the Sella Turcica.—Drs. E. E. Southard and Frederick H. Howard presented this case with photographs of the macroscopic and microscopic appearances of this tumor which Dr. Southard said had probably developed in the posterior lobe of the pituitary body.

Micrococcus Flagellatus.—This was the name given by Dr. O. Klotz, in a paper read by Dr. Adami, to a hitherto undescribed organism found in the spleen and liver, but not in the blood of rabbits during an epizootic among rats and rabbits, which he had observed.

Blank Cartridges and Tetanus.—Dr. David H. Dolly, after making careful examinations of large numbers of cartridges made by several different manufacturers, stated that he had found a tetanus like bacillus, but in his efforts to cultivate the tetanus bacillus from the cartridge he had failed, but that he had produced typical tetanus in rats by inoculation, and this he thought was sufficient evidence that the wads from which he made the inoculation contained the tetanus bacillus. He also obtained by cultivation the *Bacillus pyogenes capsulatus*. The powder, he said, was sterile.

Staphylococci in Systemic Infections.—From a study of almost four hundred and fifty cases of sepsis observed during a period of six years, Dr. Emanuel Libman, of New York, had come to the conclusion that the *Staphylococcus aureus* played a very important rôle in systemic infections, almost as important as that of streptococci. The *Staphylococcus albus* played, he thought, a very small rôle, seeming to be in the main an original invader. The staphylococcus cultures he had found only once in the blood, in a case of osteomyelitis, but he considered the finding important because it proved that the organism could cause a systemic infection. He had seen no case in which the finding of the *Staphylococcus albus* in the blood had been followed by a metastatic deposit in which the organism could be found. In the severe cases of infection by the staphylococcus aureus the organism was usually found in the urine. In several cases, multiple abscesses of the skin were found. These were most profuse in the scalp. Of the 26 cases in which the *Staphylococcus aureus* was found in the blood seven recovered.

Differentiation of Flagellar and Somatic Agglutinins in Motile Bacilli.—Dr. Henry G. Beyer, of Boston, presented the work done by Dr. A. L. Reagh and himself. The existence of flagellar and somatic agglutinins was confirmed not only through the employment of motile and non-motile cultures obtained from hog-cholera bacilli and the sera produced by them, but also through exposure of either the cultures or their corresponding sera to definite temperatures and observing the results of agglutination produced by such modified fluids. It was shown that the flagellar and somatic bodies found in the hog cholera bacilli corresponded to the Alpha and Beta bodies found by Ioos in the bacilli of Eberth, notwithstanding the fact that these bodies in the hog-cholera bacilli proved to be much more resistant to temperature than the corresponding bodies in the typhoid bacilli. Immunization experiments made with cultures heated at different temperatures resulted, moreover, in showing that the heat, while

preventing agglutinations from becoming apparent, did not destroy the power of cultures of producing agglutinins in the body of the animal as evidenced by the reactions of the sera produced with them. This interesting fact was explained on the principle of Ehrlich's theory of agglutinins, the heat being assumed to convert the agglutinogenic substances contained in the cultures into agglutinins and thus to prevent visible agglutinations without, however, destroying the substances themselves nor their power of producing agglutinins in the body of an animal exactly the same as unheated cultures will do.

Hemangio-sarcoma of the Skin of the Finger.—A case reported and described by Dr. W. McN. Miller, of Columbia, Mo. In discussing the tumor, Dr. Miller made the following classification of true blood vessel tumors with respect to the development of the endothelium. (1) Proliferation of endothelial cells in a single layer with dilatation of vessel—hemangioma cavernosum. (2) Proliferation of endothelial cells in a single layer, with new growth of capillaries and vessels—hemangioma simplex. (3) Proliferation of endothelial cells centrally with more or less obliteration of lumen—hemangioma-endothelioma intravasculare. (4) Proliferation of endothelial cells peripherally—hemangioma-endothelioma hypertrophicum. (5) Proliferation of endothelial cells after the manner of all the above given groups. Hemangioma-endotheliobłastoma. He placed the tumor described in the fifth group.

Adrenal Gland Infusion—Effect upon Animal Serum.—This investigation was undertaken by Dr. N. Gildersleeve, of Philadelphia, for demonstrating the effects upon guinea-pigs and on guinea-pigs' erythrocytes in vitrio of the serum of rabbits treated with infusions of guinea-pigs' adrenals, and of the serum of rabbits treated with small quantities of defibrinated guinea-pigs' blood. The immediate symptoms following an injection of adrenal serum into the peritoneal cavity of the guinea-pigs were marked. The animal became stupid and weak, lay on its side or abdomen, the respiration was hurried, and the heart usually rapid. The temperature quickly fell from 1 to 2° below normal, but in from three to six hours rose to normal and the symptoms usually disappeared, and in the course of a few days the animal, to all appearances, recovered from the effects of the treatment. The immediate effect following the injection of serum from rabbits treated with small quantities of defibrinated guinea-pigs' blood (1/1,000, 1/100, and 1/10 c.c.) were as a rule not as marked as when the adrenal serum was employed, but the guinea-pig became weak and emaciated, usually dying in from one to six days, showing marked changes in the blood and certain other tissues, notably the liver, kidneys and lungs, the effects to a certain extent varying according to the degree of immunization. Normal serum was employed to control the above experiments. The effects of this were as a rule but slight, in many cases the animals showing no effect of the treatment. Experiment showed that the hemolytic action of rabbit serum on guinea-pigs' corpuscles is increased by the treatment of the rabbits with defibrinated guinea-pigs' blood. Dr. Gildersleeve arrived at the following conclusions: (1) That there is something produced in the tissues of rabbits treated with washed guinea-pigs' adrenals which, when injected into guinea-pigs, produces marked symptoms which are usually transient. (2) That the serum of rabbits treated with repeated injections of small quantities of guinea-pigs' erythrocytes has, when injected, a quite marked destructive action on the blood and certain other tissues of the guinea-pig. This action depends to some extent on the degree of immunization. (3) That the hemolytic action of rabbit serum on guinea-pig erythrocytes in vitrio is increased by the immunization of these animals with small quantities of guinea-pig blood.

Epithelial Tumors of the Skin and Mucous Membranes with Special Consideration of "Carcinoma Basocellulare."—A preliminary report with lantern demonstration by Dr. Joseph C. Bloodgood. He said that in the routine study of epithelial tumors in the pathological laboratory of Prof. Halsted's Clinic in the Johns Hopkins Hospital, since June 1892, he has found from time to time a microscopic picture in which all the epithelial cells resembled the cell of the deeper layer of the epidermis. These tumors have been described in the pathological records as epithelioma of the deeper layers of the epidermis. In some instances the histological picture resembled an endothelioma, but were never considered as sarcoma. No special nomenclature was, however, adopted. Some six months ago he began a systematic clinical and pathologic study of 468 cases of epithelial tumors of the skin and mucous membrane. Very soon he became impressed that this peculiar variety of epithelioma was not uncommon. Fortunately at this time Krompecher's monograph "Der Basalzellenkrebs" appeared. At once he found that his descriptions and illustrations were identical with this variety of epithelioma, and for this reason he adopted his nomenclature—carcinoma basocellulare. Among 468 cases of epithelial tumors at least 78 (16.5 per cent.) belong to this group. This tumor arises from the skin and is situated most frequently on the nose (50 per cent., 13 out of 26 cases); skin of body (4 out of 8 cases); skin of upper lip (5 out of 10 cases); chin (2 out of 4 cases); eyelid (12 out of 24 cases); scalp (6 out of 17 cases = 40 per cent.); face and cheek (14 out of 55 cases = 33 per cent.); ear (3 out of 9 cases). In the following regions the tumor is rare: lower lip (4 out of 106 cases. In these four cases the tumor arose from the skin and not from the mucous membrane); skin of lower extremity (2 out of 22 cases); upper extremity (2 out of 19 cases); mucous membrane of mouth (2 out of 29 cases); mucous membrane of tongue (5 out of 53 cases); penis (3 out of 29 cases; in these three instances the tumor originated from the mucous membrane of the urethra near the meatus); skin of neck (1 out of 3 cases). The age of onset is usually after fifty years. The tumor grows slowly. In some instances it remains for months or years as a single lesion. It appears first as a small nodule in the skin. The thin epidermis ulcerates and a scab forms. Beneath the minute area of ulceration there is a narrow zone (2 to 4 mm.) of granulation tissue in which the basal cell alveoli are found. In some cases the disease extends and produces multiple lesions of a similar character. In this instance the surrounding skin is usually indurated. Not infrequently the disease in its growth produces a superficial ulceration which sometimes covers very large areas (6 to 14 cm.). Clinically this is the typical rodent ulcer. The fourth clinical variety appears as a fungous tumor. The elevation of the fungus above the surrounding skin may vary from 5 mm. to 3 cm., but the growth beneath the surrounding epidermis is with the rarest exceptions superficial. The small lesion may remain stationary up to fifteen years, the majority of the larger ulcers have been present over five years, many ten and fifteen years. In a very

few cases, in the more extensive lesions, the condition has become inoperable on account of deep infiltration (3 out of 78 cases). Metastasis to the neighboring lymphatics has so far been observed in only two cases. Up to the present time all the cases subjected to complete excision have remained free from recurrence from periods of a few months (recent cases) up to twelve years. Histologically the small lesion is usually composed of solid alveoli of basal cells: *carcinoma basocellulare solidum*, or the basal cell may show a glandular reticulum and arrangement: *carcinoma basocellulare adenoides*. Quite frequently the two are combined. In the extensive rodent ulcer variety one finds in a stroma of granulation tissue large stellate alveoli, and in the infiltrating parts, minute irregular alveoli, similar to the histological picture of scirrhus carcinoma. For this variety Krompecher has no terminology. In the large fungous tumors the basal cell alveoli are large, tubular in shape. Usually the center of the tubule is filled with degenerated epithelium, colloid or hyaline, or there are definite cyst formations: *carcinoma basocellulare cysticum et tubuliferum*. It is important in practical surgery to recognize this less malignant form of carcinoma of the skin and mucous membrane, because it is unnecessary to remove the neighboring lymphatic glands. A close study of the cases under Dr. Bloodgood's observation demonstrates that complete excision gives invariably perfect results. Many of the cases, over 50 per cent., were subjected to caustic applications before their admission to the surgical clinic, and quite frequently the minute lesion present at the time of the first application of the caustic has, after this treatment, begun to spread. One cannot deny that the small superficial lesion may be cured by the proper application of caustics, but he is convinced that it is by no means as certain as complete excision with the knife. The latter, properly performed, should cause even less deformity. Apparently this form of carcinoma of the skin reacts to the X-ray treatment better than any other variety of carcinoma. For this reason, if the lesion is situated on the nose, eyelid or ear, where complete excision would necessitate mutilation, it is justifiable to give the X-ray a fair trial. There is no danger in the delay, and the treatment in a certain number of cases, apparently, so far, has accomplished a cure. However, where complete excision is possible without mutilation, this method undoubtedly is the one of choice. Even in the very extensive rodent ulcers apparent healing has taken place after prolonged X-ray treatment.

Comparative Morphology of Vaccine Bodies.—Dr. James Ewing, of New York, made a preliminary report on the comparative morphology of vaccine bodies in which he showed some interesting lantern pictures of cellular and nuclear and nucleolar changes in the tissues at the point of vaccination in the skin in measles and in diphtheria.

Xanthoma.—Dr. Guthrie McConnell, presenting a case for Dr. Joseph McFarland, of Philadelphia, said that the patient from whom the specimens were taken suffered from widespread xanthoma of the face, hands, body, feet, and there was also a nodule situated within the mucous membrane of the lip at the base of the lower central incisors. Patient is an American boy of eighteen years, white; is greatly stunted in his growth and has occasional attacks of jaundice. The material examined consisted of two small masses removed from the anterior aspects of both knees. On the surface of the growths were numerous small yellow areas. Most of the changes observed in the epidermis were atrophic in nature. The rete mucosum was thin and the papillæ were in places entirely absent. The chief changes were in the reticular layer and consisted of its invasion by cells that were very characteristic. These cells, designated by many as xanthoma cells, are large and at first glance resemble very closely those of the sebaceous glands. They are sharply defined by thin but distinct walls and are flattened by mutual contact. In the central portions of the large aggregations, where they were presumably oldest, they were largest and contained the greatest number of droplets of what appeared to be fat. As one passed from the central to the peripheral portions of the cell masses it was found that with rare exceptions they possessed no definite limitations, but extended as a continuous reticulum throughout the fibro-elastic framework of the cutis vera. The peripheral extensions consisted of smaller cells of cuboidal shape, with more distinctly vesicular nuclei, with greater affinity for the stain than those of the older central cells, and contained fewer and smaller fat droplets. In those specimens that were stained to show fat the results were not satisfactory. There were in several areas numerous fine granules that to some extent showed color change, but it was not restricted to those portions that corresponded to the xanthoma cells nor was the reaction itself characteristic. The opinion of the majority of observers is that the granules are indeed fatty in nature. Is more certainly fat in xanthalasma than in the other forms of xanthoma. The cellular extension did not invade the subcutaneous tissue. One of the most striking features was the total absence of sebaceous glands. No structures that could be definitely made out as such were present. New formed capillary blood vessels were quite numerous. The first theory that suggests itself as to the histogenesis of these cells is that they are derived from pre-existing sebaceous glands. This is, however, disproved by the frequent occurrence of the xanthoma masses in the mucous membranes and in internal organs where there are no sebaceous glands. The second theory, which seems to have no foundation, is that the growths result from changes in the muscle fibers. It is finally held that the cells are of endothelial origin and are derived from the cells normally present in the lymph spaces and channels. The assumption of fat is not known to be a peculiarity of endothelial cells. The source of the fat globules is of great importance. Either they must be formed within the cells or must be conveyed to them. The general appearance would suggest that the fat is formed in the xanthoma cells and by their activity. The magnitude of the cellular characteristics and their reticular distribution make it almost inconceivable that they are cells normal to the parts which have become infiltrated with fat. All appearances justify belief that the cells belong to some genus whose members have a normal fat-forming or fat-storing tendency, and that these cells so endowed multiply and penetrate into the tissues and continue in all directions their normal tendencies. Every evidence is in favor of the connective tissue origin of these cells, but that they are endothelial in character seems to us very doubtful. According to Waldeyer, Virchow and Kaposi, we have a process going on in the xanthoma that is analagous to the formation of normal adipose tissue. They believe that the new cells grow to a considerable size and develop processes so as to form the fusiform and stellate corpuscles of connective tissue. These cells are liable to undergo fatty degeneration, but the process is slow and less destructive, and resembles the normal transformation of ordinary connective into adipose tissue. Török concludes that the xanthoma placque is composed of adipose cells inter-

rupted in their progress to complete evolution and that it is not a tumor but an excess of growth.

Trypanosomiasis.—In a report of experiments with the genus of protozoa, *Trypanosoma*, Dr. P. Ehrlich, of Frankfort-a.-Main, said that he had produced a compound which possessed decided specific action upon the *Trypanosoma equinum* (the protozoon of mal de caderas). Mice infected with this parasite were rendered temporarily immune by this substance which he has named "Trypannoth." Further experimentation he hoped would discover a compound which would cause a reaction on the part of the organisms of other animals sufficient to kill the parasite. Professor Ehrlich compared the action of the various substances (arsenic and benzopurpurin) which had been found to produce what had proved a temporary immunity to the Trypanosoma, to the action of quinine in malarial infection.

Lymph-nodes in Hemangioma of the Orbit.—Dr. Aldred Scott Warthin, of Ann Arbor, Mich., presented a large number of lantern slides illustrating this subject and said that in a tumor of the orbit which had grown slowly for twenty-three years and which microscopically presented the structure of a hemangioma cavernosum, there were found numerous typical lymph-nodes with characteristic germinal centers. The nodes were so numerous that eight to twelve could be found in a single section. The development of such nodes and germinal centers could be easily traced. Two modes of formation were seen. In one there was at first a proliferation of the endothelium and perithelium of the blood spaces forming a reticular network extending across the lumen of the blood space. In this reticulum lymphocytes gradually collected, and from the further proliferation of the endothelium at certain points germ centers were formed. Free red blood cells were found in the spaces of the reticulum, and about the follicles a more or less perfect blood sinus was developed. The new nodes therefore presented the structure of hemolymphatic tissue rather than of ordinary lymphatic. In the second mode of formation there was at first a proliferation of the endothelium of a capillary in the connective-tissue trabeculæ separating the blood spaces. As a result of this proliferation there was first formed a typical germ center about which the lymph follicle gradually developed, the lymphocytes apparently arising from the germ center. All possible transition stages of both modes of formation could be seen. The formation of the lymphoid tissue appeared to be entirely secondary and not to constitue an integral part of the tumor structure. Stasis probably plays the chief part in its development, and with this factor there is probably associated a more embryonal character of the endothelium of the blood spaces of the tumor.

The Occurrence of Myeloid Changes in the Hemolymph Nodes.—(Dr. Warthin.) In a number of cases of leukemia and in one case of fatal anemia following prolonged and repeated small hemorrhages from the nose there were found in the retroperitoneal hemolymph nodes changes that could be interpreted only as of a myeloid character. Neutrophile and eosinophile myelocytes, bone-marrow giant cells as well as a great variety of non-granular mononuclear forms and atypical lymphocytes were present. Given sections of the nodes could not be distinguished from given sections of bone-marrow. In the leucemic cases the process was regarded as of the nature of metastasis, in the hemorrhagic case as a reversion to an embryonal form of blood-formation. While under normal conditions mononuclear eosinophile and cells resembling bone-marrow giant cells are almost always to be found in the hemolymph nodes, there is no reason to believe that these nodes ordinarily play any part in hematopoiesis. The occurrence of such marked myeloid changes in the nodes as found in the case of fatal anemia is probably to be regarded as of the nature of a compensation for the bone-marrow.

Eosinophilous Transformation of Lymphocytes; the Formation of Eosinophiles in the Hemolymph Nodes; the Relation of Eosinophiles to Hemolysis.—Dr. Warthin said that mononuclear eosinophiles are almost constantly present in small numbers in the hemolymph nodes, and under certain conditions they may be found in these organs in great numbers. In such cases all possible transition forms between lymphocytes with eosinophile granules and the polymorphonuclear eosinophiles are seen. The morphological evidence may be taken as favoring the view that eosinophile polymorphonuclears may be found from lymphocytes. Such findings oppose the generally accepted view of Ehrlich as to the origin of the eosinophile cell. In all cases in which there is hemolysis of the eosinophiles of the hemolymph nodes are increased in number. In some instances nearly all the cells of a node may show eosinophile granules. The relation of the products of the destruction of the red cells to the formation of the eosinophile granules is not a direct one, but it is possible that the granules represent further elaborated products of red cell disintegration.

Hemolymphotoxin.—Dr. Warthin read this paper for Mr. Harro Woltman, of Ann Arbor, Mich., in which he said that a comparative study had been made of the effects produced by the injection of the sera of geese made immune to sheep's blood, spleen, bone-marrow, lymph glands and hemolymph nodes. In the sheep injected with such immune sera the changes in the blood as well as in the tissues are identical in kind but differing in degree. All the sera were hemolytic, lymphotoxic, myelotoxic, and endotheliotoxic, the results of the injections varying only in intensity. The sera of geese made immune to injections of emulsions of sheep's hemolymph nodes produced a more intense action than the sera of those made immune to spleen, bone-marrow, etc. The hemolymphotoxic serum caused greater hemolysis than serum immune to sheep's corpuscles. When heated the hemolymphotoxic serum lost the greater part of its hemolytic power, but not all. Injections of such heated serum caused a marked proliferation of the endothelial phagocytes in the sinuses of the hemolymph nodes.

Action of Antistreptococcus Serum.—Dr. D. H. Bergey, of Philadelphia, read a paper on studies made by him on the action of antistreptococcus serum.

The Biochemistry of the Tubercle Bacillus was discussed by Dr. P. A. Levene, of New York, and he also read a report of work done by Dr. L. B. Stookey and himself on Autolysis.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 2, 1901.

President *pro tem.*, Joseph Fraenkel, in the Chair.

Case of Huntington's Chorea.—This was presented by Dr. J. Ramsay Hunt. The patient was a Hungarian, thirty-three years old, the youngest of seven children. He had been a resident of the United States for six years he had twiching movements of the upper extecedents could be elicited. From the patient's sister it was learned that he was extremely dull, even as a child, and lacked interest in his studies. For the past three years he had twitching movements of the upper extremity, confined chiefly to the fingers and wrist of the left arm. Similar muscle-twitching was also present in

the left lower extremity, consisting of slight flexion movements in the ankle and toes. Occasionally, the left quadriceps extensor contracted, elevating the patella. The face was the seat of irregular grimaces and twitchings, and the latter were also present in the tongue, interfering at times with speech. These movements were at no time violent, and seemed to be increased by voluntary movements of the parts. The left upper extremity was complained of by the patient as feeling cold and heavy, and interfering with finer movements of the hand, such as eating. Mentally, the patient was dull. He was cranky and irritable at times, careless in his dress, and was unable to obtain any employment. At times, he had mild acute mental symptoms and apparent hallucinations. He had complained of frontal headaches at intervals since the onset of the trouble. Otherwise, the examination proved negative. Muscular power was unimpaired; there was no ataxia; no sensory disturbances. The pupils and all reflexes were normal. He had never had a convulsion.

Dr. Hunt said that the character of the twitchings, although slight and limited to the left side, resembled those observed in Huntington's chorea. The constancy of the symptoms, the pronounced and progressive character of the mental changes, even in the absence of heredity, pointed very strongly to a degenerative form of chorea. An initial psychosis with secondary motor manifestations would deserve consideration in the differential diagnosis.

Case of Multiple Cerebellar Tumors.—Dr. B. Sachs presented the specimen of a case of multiple cerebellar tumors. These had given rise to the usual symptoms of a cerebellar neoplasm. There was marked ataxia of the left upper extremity, and a tendency to fall to the left. The skull was trephined for the purpose of relieving pressure and preventing the development of complete blindness. The patient died from shock a few hours after the operation.

Cerebrospinal Lues (Syringomyelia Symptom Complex).—This was presented by Dr. Isador Abrahamson. The patient was a male; thirty-five years old; single; a pedler, and a native of Rumania. When he was eleven years old, after a fright, he became blind in the right eye and the vision of the left eye became impaired. Some improvement in sight occurred within two months. When he was sixteen years old he contracted a chancre, with the usual secondary symptoms. He was treated for this disease for one year with both external and internal remedies. He was moderately addicted to the use of alcoholic stimulants, and smoked excessively. About six years ago he developed an abscess on the left side of the neck. This was incised and drained. Subsequently, he suffered from pains in the left upper extremity and left side of face; these were shooting in character and were accompanied by paresthesias over the same areas. Later, he suffered from weakness in the left hand, with beginning atrophy, and his voice soon assumed a raucous character. Five years ago he developed a luetic keratitis in the right eye, which cleared up under insufflations of calomel. About this time swelling of the fingers was first noticed. Two years ago he again had difficulty with his eyes, with temporary blindness, and blueness and limitation of vision. He had frequent attacks of diplopia during the past six years. Since last summer he had repeated crops of vesicles on fingers, with beginning wasting and simultaneous weakness of the right hand. At irregular intervals there was interference with urination, now retention, now slight incontinence. Also some difficulty in defecation, with constipation and diminished sexual power. He suffered from headaches on the left side, with some vertigo and tinnitus aurium and loss of hearing on that side.

Status praesens.—General enlargement of the lymphatic glands, many stigmata of degeneracy, convergent strabismus due to weakness of both external recti; marked nystagmus, rotary in character, especially in lateral positions; eyes prominent; Von Graefe symptom present; pupils irregular, the right being larger than the left. Both light and consensual reactions were sluggish; the accommodative reaction much prompter. Vertical axes of eyes not parallel. Right lower facial innervation stronger than the left; jaw-jerk present; right pharyngeal stronger than the left; pharyngeal reflex present. Hands blue and congested; fingers thickened, with small, rounded vesicles of various size scatttered over them. Thenar wasting, more pronounced on the left side; hypothenar wasting less marked. Reaction of degeneration in some muscles; marked loss of power in hands and forearms; more marked on the left side. Deep reflexes of the uppper extremities diminished. Heart, lungs and other viscera apparently normal. Knee-jerks active, especially the left; likewise the Achilles reflex. Tactile sensibility was practically normal. There was disturbance of the pain sense, chiefly analgesia, over the chest and upper extremities, principally on the left side, and thermanesthesia for both hot and cold over the same areas. Deep muscular sensibility was disturbed in all four extremities. Vision, O. S., 6-200; O. D., 20-200; marked staphyloma posticum; detachment of retina in left eye, downward and outward. The changes were very suggestive of a luetic origin. To sum up, the case was probably one of cerebrospinal lues, presenting the syringomyelic symptom complex, or else it was a case of syringomyelia, plus lues, or possibly of luetic origin. Such cases, the speaker thought, were rather uncommon, and were naturally of considerable clinical importance.

Dr. Sachs, in discussing this case, said he had seen some cases which, while luetic, presented the clinical aspect of syringomyelia. He regards these cases as examples of cerebrospinal lues, not luetic syringomyelia.

Flaccid Luetic Hemiplegia with Atrophies.—Presented by Dr. Abrahamson. The patient was a male, twenty-six years old; married; a Russian pedler. He was an excessive smoker and used alcoholic stimulants in moderation. He had lues four years ago. Ten years ago he had an attack of parasitic alopecia, and six years ago he sustained a severe fall. This resulted in a Colles' fracture and he was said to have been unconscious for a long time. About two months ago he was obliged to remain in bed for three weeks on account of stiffness of the neck, violent neuralgic occipital pains, and headaches, chiefly nocturnal. During the third week of this illness he began to suffer from severe right-sided headaches, with vertigo. Three weeks ago, while in a café, he felt dizzy and staggered as though drunk. He fell to the floor and found that the right side of his body was numb and paralyzed. Speech was also lost. This condition lasted about five minutes, when he apparently again felt normal. A short time afterward he had a second attack lasting five or six minutes, and in the course of two hours he had four additional similar attacks. From the sixth attack, however, he failed to recover; speech was lost for four days and the paralysis still persisted. At the present time there was paralysis of the lower two-thirds of the right face and of the right upper and lower extremities. There were dropped wrist and foot on the right side; flaccidity of the right hand and forearm; also the leg and foot. Decided wasting in right posterior forearm musculature; also, but to a lesser degree, in the right leg. The electrical reactions in the posterior forearm were much diminished; myotatic irritability diminished; sensibility intact; heart normal.

Dr. Abrahamson said that in view of the electrical

changes, the marked wasting, flaccidity and altered myotatic irritability, all occurring within three weeks after the onset of the attack, he felt justified in calling the case a flaccid hemiplegia with atrophy.

Jacksonian Epilepsy of Luetic Origin.—Presented by Dr. Abrahamson. The patient was a male, thirty-nine years old, a shoemaker by occupation and a native of Hungaria. He was married and the father of eight children, of whom six were living. His first wife had three miscarriages occurring about the third or fourth month. The patient had typhoid fever in childhood. He was a heavy smoker and a moderate drinker. He positively denied venereal infection. His present illness dated back to Dec. 15, 1903, when he began to suffer from frequent attacks which were ushered in with a feeling of numbness in the right hand, followed by a drawing in of the thumb, flexion of the fingers and semipronation of the hand. The numb sensation spread to the shoulder, then down to the hip and feet. He complained of weakness of the leg and had to sit down to keep from falling. Speech was also temporarily lost. Each of these attacks, which sometimes occurred at hourly intervals, lasted about fifteen minutes, and were followed by some weakness of the right side and slight dizziness. He also complained of left-sided headaches and slight nausea and epigastric distress at the end of the attack. There was also rolling of the eyes during the attack, and rolling of the tongue upon attempting to speak. No frothing; no biting of the tongue; no diplopia. Micturition and defecation were not affected. There was no loss of consciousness. An examination showed that the right pupil was larger than the left. The pupillary reactions and ocular movements were normal. There was weakness of the entire right half of the body, including the lower two-thirds of the face. There was some exaggeration of the deep reflexes on the right side. The special senses were normal. The eyes showed a beginning papillitis.

The patient was put upon inunctions of mercury and large doses of potassium iodide. At first, the weakness on the right side increased, and a right hemianesthesia of somewhat irregular distribution developed. Subsequently, he improved rapidly, and at the present time he had entirely lost his attacks, the right-sided weakness was much less, and only scattered areas of diminished sensibility were present over the right side.

Arteriosclerosis of Spinal Cord, with Hemorrhage.—This case was presented by Drs. Joseph Collins and Edwin G. Zabriskie. M. H., a fireman, with no particular antecedents, noticed toward the end of 1902 fatigue on exertion, jerking sensations, occasional sharp pains in lower extremities, and a sensation of heaviness, accompanied by difficulty in holding his urine. These symptoms steadily progressed, until he awoke one morning and found himself unable to stand or walk. There was also incontinence of the bowels and bladder. On examination, it was found that he was unable to flex his thighs slowly, and there was slight atrophy of the left anterior and inner thigh muscles. The reflexes were absent; Babinski's phenomenon present. Power in the upper extremities was fair, but he was easily fatigued. There was slight quantitative diminution of sensation in both lower extremities, and a zone of hyperesthesia as wide as the hand above the trochanters. There was slow speech and mental reflex. Also a moderate degree of general arteriosclerosis. Death supervened gradually of cardiac weakness. Autopsy: Macroscopically, there was arteriofibrosis everywhere, only slightly marked in the brain and bulb, but very marked throughout the cord. The vessels were distended with blood, and there was some extravasation into the perivascular spaces. The changes consisted in thickening of the media and propria, with loss of muscular tissue. A hemorrhage was found in the ninth dorsal segment of the cord, involving the right posterior and left anterior horns. There was sclerosis of the glia around the margin of the cord and in the lateral pyramidal tracts. Secondary degenerations were found in marginal portions of the right column of Goll, Gowers and the direct cerebellar tracts on both sides above the lesion, and the crossed pyramidal tracts, and columns of Türck below the lesion. There was no definite degeneration of Schultze's tract or the other descending tracts of the posterior columns, excepting in the lower lumbar region, where a small area in the triangle of Gombault and Phillippe was apparent.

Dr. Zabriskie said it was interesting, in view of the difference of opinion as to the origin of the fibers in the descending tracts of the posterior columns, to note that in this case, although the right posterior horn was almost completely destroyed, the comma tract and areas of Flechsig and Phillippe-Gombault were not involved; this would seem to point to the exogenous origin of these fibers.

Report of Two Cases of Tumor of the Pontomedullocerebellar Space (Acoustic Neuroma) with Operation.—By Drs. J. Fraenkel and J. Ramsay Hunt. *Case I.*—Reported by Dr. Fraenkel. Operation by Dr. Charles A. Elsberg. The patient was a man, forty-eight years old, a theatrical manager, who entered the Montefiore Home on July 1, 1903. One brother was an imbecile; otherwise his family history was negative. His previous personal history was also without bearing on the present condition. He denied excesses and venereal infection. About five years ago the patient first noticed that his hearing on the right side was impaired, so that he had to use his left ear when at the telephone. A year later his gait became staggering and uncertain, and he could not coordinate his lower extremities at all times. The right lower extremity was the first to be affected. The patient did not notice that he swayed to one side more than to the other. Three years ago his gait frequently was like that of a drunken man, and two years ago a transient diplopia was noticed. About the same time the lower extremities became markedly spastic, his sight became impaired, his speech became stammering, and he noticed that he was tremulous when writing or performing any other intentional function with the upper extremities. During the last year, occasional insufficiency of the sphincters was noticed and he was unable to walk without assistance. At no time was there any pain, paresthesia or girdle sensation. An objective examination showed static and locomotor ataxia. Romberg's symptom was present. The patient falls and inclines to the left side. There is slight mental hebetude and occasional emotional explosiveness. There was motor weakness of all four extremities, particularly on the left side; a tactiform unsteadiness of both upper extremities, particularly of the right; loss of position sense in right-sided upper extremity; exaggeration of reflexes, particularly on the left side; Babinski present on both sides, more marked on the left; marked nystagmus; scanning speech; considerable choked disk, with retinal hemorrhages; deafness of the left ear. Six weeks before operation, a paralysis of all branches of the seventh nerve set in, with marked changes of the electrical reactions. The operation for the removal of the tumor was performed by Dr. Elsberg. The patient unfortunately died from what appeared to be an acute uremia thirty-six hours after the preparatory operation.

Dr. Charles A. Elsberg, who did the operation in this case, said that the opening in the skull was made in a rather unusual situation. In most of the operations for a tumor in the posterior fossa, the cerebellum was ex-

posed by the so-called, occipital craniotomy, in which the opening was made in the occipital bone somewhere between the median line and the posterior margin of the mastoid, and below the level of the lateral sinus. For tumors situated in front of the cerebellum, as was the tumor in this case, and for tumors in the anterior and lateral parts of the cerebellum there were several objections to this method of exposure: (1) It was not the shortest route from the surface of the skull; (2) the manipulations in the removal of the tumor must be done by the sense of touch alone; (3) even with the most gentle manipulations the cerebellum was apt to be contused and its tissues lacerated; (4) in the digital examination of the anterior parts of the cerebellum from the under surface of the organ the finger must come in frequent contract with the medulla and perhaps the pons, and the great danger from even slight injury to these structures was well known. Dr. Elsberg said he investigated this subject for the purpose of finding, if possible, a method by which the disadvantages above mentioned would be avoided. Actual measurements on a number of skulls showed that the shortest distance from the surface of the skull to the anterior edge of the lateral lobe of the cerebellum on the same side was measured on a line which ran along the posterior surface of the petrous portion of the temporal bone, and reached the surface of the mastoid 1 to 2 cm. behind the external auditory meatus. The distance from the outer surface of the occipital bone, below the level of the lateral sinus, to the anterior edge of the cerebellum diminished steadily as the measurements were made more and more distant from the median line. These facts showed that the shortest route to the pontomedullary space on the same side would be through an opening made in the mastoid process. If, in the cadaver, an opening was made in the mastoid region and the dura incised, the lateral edge of the lateral lobe of the cerebellum fell away from the posterior surface of the petrous portion of the temporal bone, so that full one-half of that part of the bone could be seen. With only very slight retraction, the lateral lobe could be drawn sufficiently toward the median line so that the auditory and facial nerves could be plainly seen in their course from the pontomedullary cerebellar space to the internal auditory meatus, and even the 9th, 10th and 11th cranial nerves could be seen in part of their course in the posterior fossa. The auditory nerve could be cut close to its origin with a fine scissors without touching the pons or medulla. Dr. Elsberg said he had performed the operation on the dead body a number of times and was convinced of its feasibility. In the living body, where the cerebellum was filled with blood, the same conditions would be found, although to a somewhat lesser degree. This had been demonstrated by Krause, of Berlin, in a somewhat similar operation devised by him in a case in which he cut the auditory nerve in the posterior fossa for the relief of a persistent tinnitus aurium. As was well known, considerable of the lateral parts of the cerebellum could be cut away without causing a permanent disturbance in the functions of this part of the brain. Therefore, this was the part of the cerebellum that could be handled with the greatest safety, and at the same time, could be most easily retracted. From these facts it followed that the approach to the anterior edge of the cerebellum along its outer edge was not only the easiest, but also the route by which the organ was least apt to be injured during manipulations. An examination into the anatomical relations of the parts in the posterior fossa would soon make it clear that when the pontomedullary cerebellar space was approached from the mastoid region along the outer edge of the lateral lobe of the cerebellum, neither finger nor instrument need come in intimate contact with the pons or medulla until the space itself had been reached. It was probable that the correct way to remove tumors from this region was to expose the structures on the central side of the tumor, if possible, and first divide these, and then to work outwards all of the time, away from the pons and medulla. Hence, with this lateral method, the danger of wounding these important structures was reduced to a minimum.

Dr. Elsberg thought it was advisable, in almost all of these cases, to operate in two stages. On Jan. 21, 1904, under chloroform anesthesia, the bone was exposed by a flap of the soft parts, including the periosteum over the mastoid and outer parts of the occipital regions. An opening was then made with the cranial drill, chisel and rongeur, measuring 5 by 8 cm., and extending from above the superior curved line of the occipital bone to within 1½ cm. of the margin of the foramen magnum, and from within 1 cm. of the external auditory meatus to 3 cm. from the median line. In the upper part of the wound the occipital lobe, covered by its dura, was visible, and in the lower part, the right lobe of the cerebellum, covered by its dura. The greater part of the lateral sinus of the right side was thus exposed. The wound was then closed, the flap being sutured back into place, and a voluminous dry dressing was applied. The patient was considerably shocked at the end of the operation, but he reacted well to stimulation. His condition remained fairly good until the second day, when his kidneys ceased to act and he passed into a uremic condition and died in forty-eight hours. The skin-flap was turned back about two hours after death and the dura incised. With the head turned to the side, the tumor could be plainly seen at a depth of from 3 to 4 cm., and when the finger was introduced it was found that the tumor could be peeled out with the greatest ease. It seemed probable that had the patient survived the first operation, the removal of the tumor could have been accomplished at the second operation in a short time and with very little difficulty. After the patient's death it was learned that he had had an attack of acute nephritis, with general edema, some years before, and although the urine had been carefully examined prior to the operation and had showed no evidence of renal disease, it was just to suppose that long-standing kidney trouble was the probable cause of the acute suppression of urine after the operation.

Case II.—Reported by Dr. Hunt. Operation by Dr. George Woolsey. This patient was a pedler, forty-two years old. Six years ago he began to suffer from an annoying tinnitus in the left ear, followed by some impairment of hearing. During the past four years he has had occasional occipital headaches, with vertigo. These symptoms gradually increased in severity and were accompanied by cloudiness of vision. For the past six months there has been unsteadiness of gait. When he first came under Dr. Hunt's observation, the watch tick was not perceptible with the left ear, and the tuning-fork was very faint to aerial and bone conduction on that side. There was paresis of the left seventh nerve, more apparent in its upper branch, with slight quantitative electrical changes. There was paresthesia in the sensory distribution of the left fifth nerve, with objective sensory disturbances. The pupils were unequal, the left being wider than the right. Reactions were present. There were amblyopia and choked disks, and a slow nystagmus in extreme positions. There were hemiasynergia and hemiataxia of the left side. In falling, the patient favored the left, and progression was decidedly to that side. The nuclear reflexes were active; the knee-jerks exaggerated, the left more so than the

right. There was no ankle-clonus. The skin reflexes were present; no Babinski. The diagnosis of a neurofibroma of the left acoustic nerve was made, and operation was advised. From the known pathological character and relation of the surrounding structures of this variety of tumor in general, it was possible not only to localize the growth, but to state in general terms its situation in the pontocerebellar space outside of the brain substance, its possible size and consistence, and its enucleability. Its attachments to the surrounding structures consist only of the leptomeninges, blood vessels and adhesions, and when these are divided it would be possible to lift the growth out of its socket in the brain with ease. With these data at his disposal, Dr. Woolsey decided on entering the occipital bone on its posteroinferior surface, to the left of the median line and below the lateral sinus. The index-finger was inserted through the trephine opening and beneath the left cerebellar hemisphere, coming in contact immediately with the nodular surface of the growth, which was broken up by gentle manipulation and removed in fragments. There was a tendency for the cerebellar hemisphere to rise into the trephine opening, and this, with the digital manipulation caused some laceration of its substance, with oozing. Following the removal of the growth, the respirations of the patient became irregular and shallow, with occasional alarmingly long intervals. The pulse was rapid. The operation, which was done under ether, had required nearly two hours. At 5 P.M., three hours after the completion of the operation, the patient's temperature was 102° F.; pulse, 112; respirations, 26. The breathing had improved in character, and the patient seemed to be reacting. Slight clonic twitchings of the left side of the face were noticeable. Death occurred at 1 A.M., apparently of respiratory and cardiac failure, just twelve hours after the operation. Permission was obtained to remove the brain only. The outer surface of the dura was dotted here and there with little tufts and excrescences, which proved to be attached to the brain cortex and when torn away, they left minute depressions, with a punched-out border. Examination of the base showed that the tumor had been almost completely removed, only two small fragments remaining, together with a small blood-clot, scarcely larger than the little finger-nail. The inferior surface of the cerebellum was lacerated, but there was no external evidence of injury to the pons and medulla. The general ventricular cavity of the brain was dilated, showing that there had been a not inconsiderable internal hydrocephalus. Upon splitting the *worm* of the cerebellum, Dr. Hunt said he was surprised to find a firm, rounded projection from the left side of the floor of the fourth ventricle, corresponding to the site of the *tumor*. Microscopic sections through the brain proved this to be an extensive edema and hemorrhagic infiltration of the left peduncle of the pons, evidently arising from the region of the lacerated cerebellum and gradually encroaching on the vital centers of the medulla. This internal pons hemorrhage was probably the immediate cause of death.

Dr. George Woolsey said he was much interested in the class of tumors described in the cases reported by Drs. Fraenkel and Hunt, for they were so definitely localizable and could be so readily enucleated that they were very suitable for surgical treatment if they could be successfully exposed. He believed that this could be done. In the case he had operated on several months ago, which was referred to him at Bellevue Hospital by Dr. Hunt, he knew of no previous experience to serve as a guide in the operation. The tumor was approached from behind and the side by removing a large area of bone, comprising all that part of the occipital bone below the superior curved line and to the left of the median line. The opening left only a narrow bridge of bone between it and the foramen magnum, and extended forward into the mastoid until the bone became very thick. Passing the finger beneath the cerebellum, the tumor was felt and removed piecemeal. This necessitated introducing the finger a number of times, and there was some laceration of the lateral lobe of the cerebellum which did not seem of any moment. The tumor was larger than he had expected to find it. In another case he would try to pass a forceps along the finger, seize the tumor, enucleate it with the finger and remove it entire. The plan of operating in two stages, recommended by Horsley and employed by Dr. Elsberg he thought was most excellent where the exposure was prolonged and much blood was lost. He thought Dr. Elsberg's method of approach had much to commend it, although it was not so much nearer the site of the tumor than the opening he had made as might be inferred. It had the objection that the bone was very thick, so that too much time, and perhaps blood was lost in getting through it. In operations on brain tumors it was important not to take too much time in the exposure alone. This objection was obviated by operating in two stages. Dr. Woolsey said the entire operation in his case took no longer, if as long, as the exposure in Dr. Elsberg's case. After the operation, his patient seemed in good condition and appeared to suffer but little from shock, but symptoms of the latter appeared several hours later, and he failed to rally. On the whole, in another similar case, he would be inclined to operate in two stages and by the lateral approach suggested by Dr. Elsberg.

Dr. George E. Brewer said he had been interested in the subject of cerebral tumors for many years. He had twice explored the posterior fossa, in the first instance finding a sub-cortical cerebellar growth of tuberculous origin, which was successfully removed, the patient making an excellent operative recovery. He died some months later, however, from general tuberculosis. In the second case the patient succumbed after an extensive bone removal, undertaken simply to relieve pressure. A number of anatomical investigations carried on in the dissecting room of the College of Physicians and Surgeons led the speaker to advocate the plan of opening the skull by removing, practically, all of the bone below the superior curved line to within half an inch of the foramen magnum below, and from the median line to a point half-an-inch behind the mastoid. By opening the dura, the finger could be easily passed behind the lateral lobe and reach the situation of these tumors at a depth of less than an inch and one-half from the surface of the wound. Of course, adequate exposure to remove such a growth would necessitate the destruction of a portion of the lateral lobe: this, however, could be done without serious trouble to the patient, as had been demonstrated in his first case. It was Dr. Brewer's opinion that speed of operation was perhaps the most important factor necessary to success, as these patients almost invariably died if the operation was at all protracted. He was in favor of doing the operation, when practicable, in two stages. The first operation should consist of the removal of the bone only, which to a certain extent relieved the pressure, and at a subsequent period the dura should be incised and the tumor removed. He thought the primary operation should be done in from twenty to thirty minutes.

Dr. Hunt, in closing, referred to a previous communication, published in conjunction with Dr. Fraenkel, in which five cases of tumor of the pontocerebellar space were recorded. In that paper, especial stress was laid on the certainty of localization and the enucleability of this group of tumors, and their surgical importance.

In both of the cases under discussion, in which operation was attempted, the diagnosis of an acoustic neuroma was made, and the operative procedure was modified to meet the known anatomical peculiarities of this type of tumor. In Case I the patient succumbed thirty-six hours after the performance of the first stage of the operation, apparently from shock, although a renal complication could not be excluded. In Case II death was due to laceration of the cerebellum, with resulting effusion of blood into the tissues of the medulla and pons. Both of the operations were prolonged and tedious, and considerable trauma was inflicted in removing the thick occipital bone, and enlarging the trephine openings. It seemed of paramount importance, in exposing tumors in this locality, that the operation be done expeditiously and with great gentleness, as any concussion must be especially effective in this region. The division of the operative procedure into two stages was also to be recommended.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held March 21, 1904.

Two Cases of Gout in Negroes.—Dr. Futcher reported these cases. The first was a man of thirty-one years, who was admitted to the hospital complaining of dyspnea and rheumatism. He had had no infectious diseases except measles. There was a marked alcoholic history extending over many years. About six months previously he had had an attack of "rheumatism" in the left big toe joint from which he recovered. On admission the same joint was swollen, red and sensitive. The heart was enlarged and there were physical signs of mitral stenosis and insufficiency and of aortic insufficiency. The acute gout subsided; but the patient was again admitted some weeks later with signs of broken compensation (cyanosis and edema). The symptoms cleared up but about two months subsequently the patient was admitted for the third time, complaining of dyspnea and edema. He died, in a semicomatose condition, within twenty-four hours. Autopsy showed a mitral insufficiency and stenosis, aortic insufficiency and a sodium-biurate deposit in the synovial membrane of the big toe-joint. Dr. Futcher thought that there was probably no relation between the gout and the heart condition. The second patient, a man of twenty-four years, was admitted with anemia, puffiness of the eyelids, and marked headaches. The urine contained albumin and casts. There was swelling of the left big toe-joint with pain and tenderness, but this disappeared in two weeks. Headaches became worse, coma appeared and death followed. Autopsy showed a chronic interstitial nephritis of the "small white" variety. The interest of these cases lay in the rarity of the disease in negroes, no other case having occurred at the Johns Hopkins Hospital.

Relation of Uric Acid to Gout.—Dr. Schmoll spoke on this subject. Two theories have been advanced: one based on retention due to the failure of the kidneys to excrete (Garrod) and the other on an actual increase in formation of uric acid. Neither theory, however, is tenable. Gout may be due to precipitation of uric acid from the blood (for it exists there though not detectable on account of its combination with thymic acid), or to an actual synthesis.

Piezometer.—Dr. Kelly showed a new instrument recently devised for him for accurately recording the findings of palpation, substituting an objective method for the subjective touch sense. It is called a Piezometer and registers differences of hardness and softness, of rigidity and of pressure needed to cause pain.

Myomectomy in its Relation to Pregnancy.—Dr. Kelly also read this paper. Formerly in all cases of myoma panhysterectomy or supravaginal hysteromyomectomy was done; but with improvement in technic myomectomy has been more commonly practised. Two hundred and thirty-one such operations have been done at the Johns Hopkins with six deaths. The following are the reasons for the procedure: (1) It removes the disease without the uterus. (2) It avoids menstrual disturbance and an artificial menopause. (3) It allows conception. (4) It does not cause the mental distress which accompanies removal of the uterus. Of 140 subjects reviewed by Dr. Kelly from his own work four have conceived. The patients presented various types and sizes of myoma; two of them have borne full-term children, one miscarried and one is now pregnant. Schauta, Wurder and Olshausen have reported cases of conception following myomectomy, but there is no series which shows quite this proportion of successes.

Dr. Noble said that he was a myomectomist but not an extreme one, believing in the operation under a number of limitations. The woman should be under thirty-five years, the tumors small in size and number, the patient's full consent gained for the more dangerous procedure, and a strong desire for children present. He knew of at least two children born of women on whom he had performed myomectomy.

Observations on the Subclavian Artery in Man.—Dr. Bean reported these, which were made in the dissecting rooms of the Johns Hopkins Anatomical Laboratory. Two hundred and nineteen subjects were studied and five general types of the artery observed. Four anomalies were found: (1) A lateral thoracic artery in 5 of 28 cases. This may have clinical importance in broken rib, tapping of the pleura or resection of a rib. (2) Thyroida in an artery supplying the lower half of the thyroid gland, of clinical importance in tracheotomy and surgery of the thyroid. (3) An anomalous right subclavian artery. (4) An anomalous origin for the arteries from the first and second parts of the subclavian.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section on Clinical Medicine and Surgery.

Stated Meeting, held March 18, 1904.

Pneumonia.—Dr. Pleasants read a paper on the statistics of this disease and exhibited a chart showing the mortality curve for tuberculosis and pneumonia during the past fifty years. The former has steadily fallen and the latter steadily risen. The banner years for pneumonia deaths in Baltimore being 1900 and 1903-'04. The mortality from pneumonia this year though large has been exaggerated by the newspapers. Exposure at the time of the fire, and unusual climatic conditions have been suggested as the causes, but there is little proof for either. The large negro population of Baltimore of course accounts for a great number of the cases here. The total death rate in that race being twice that of the white. The morbidity of the disease is hard to estimate, and whether the mortality increase of the last fifty years is really due to an increased number of cases or an increase in the fatality it is impossible to say. The following factors must be considered in explaining the increased mortality of the disease: (1) Increase in the density of the population; (2) general prolongation of life, and reduction of intestinal diseases among children; (3) climatic fluctuation; (4) increase of immigration; (5) the negro element; (6) more accurate diagnosis, with better autopsies and death reports; (7) decrease

of death rate from tuberculosis; (8) the presence of influenza, with which pneumonia is evidently closely connected; (9) a theoretical increase in the virulence of the pneumococcus.

Bacteriological Knowledge Concerning Pneumonia.—Dr. Welch dilated on this subject. In spite of the complete studies of the disease, this knowledge has had practically no influence on the clinical attitude. The organism first discovered by Sternberg in 1880, confused with bacillus by Friedländer in 1883, and clearly described in 1886 by Fränkel and Weichselbaum, is found in all cases of true lobar pneumonia. It is a delicate organism, but by proper methods can always be demonstrated. It is characterized by short viability in cultures and in the body, and by its causing a local inflammation, but it also sets free a toxin (causing the pneumonic fever of Flint). Following the discovery of the toxin of diphtheria and tetanus attempts were made to produce a similar substance for pneumonia. This, however, is bacteriologically an impossibility, and the evidence that the pneumococcus produces a toxin is entirely clinical. The organism is thought by some to be only a variety of the streptococcus. It is harbored normally by 20 per cent. of all people, and the accessory causes of pneumonia are therefore almost the efficient causes. In fact, there is no disease in which such emphasis must be laid on the so-called accessory causes. It is hard to decide to just what extent the disease is contagious, but there is no bacteriological basis for making it a reportable disease. It is unknown in Arctic expeditions which would seem to point against exposure as one of its causes. It may cause septicemia. The immunity which it produces is in human beings only transitory. A definite artificial immunity, though of not a high degree, is easily produced, and the serum from animals so immunized undoubtedly protects against the disease. But all antibacterial (as distinguished from antitoxic) sera are uncertain, and this is exceedingly true of the pneumonia serum, the clinical value of which is of very great doubt.

Hospital Experience.—Dr. Osler discussed pneumonia as he has seen it in his hospital experience. One of the striking features of the disease is its sameness. In the past twenty-six years he had studied the disease in three large hospitals in various parts of North America, but its clinical features were always uniform. This is particularly true of the mortality, which Dickerson showed several years ago to remain (when large numbers of cases are considered) absolutely uniform. In the Johns Hopkins Hospital the average mortality has been 26 per cent., and the same figures hold for the Massachusetts General Hospital, for the Montreal General, and for Blockley. In private practice of course a smaller proportion of deaths is seen, but terminal pneumonias are often overlooked here, ether pneumonias are very rarely seen, and other causes operate to reduce the mortality. There is no disease the familiarity with which can be more valuable to the student than pneumonia, and at the Johns Hopkins the students are thoroughly drilled by constant clinical contact with this disease and with typhoid.

Therapeutic Side of Pneumonia.—Dr. Atkinson discussed this side of the question. Pneumonia is largely a local inflammation and it ends by crisis. The body is therefore limiting the disease anatomically and preparing in the end to overcome it which, if undisturbed, it can do. The indications then are plainly (1) to aid the natural tendency to recovery, (2) not to interfere with it (as for instance by the administration of nauseating expectorants). Some of the cases will die and others will get well, no matter what we do, but between these two classes lies the field for therapeutic interference. There is of course no specific for this disease. Bloodletting, veratrum viride and sera, whatever their value, are not specific. Bloodletting is too much neglected, and is particularly of value when the right heart is overdistended. The therapeutic rule should be to go slow with treatment, to watch the case carefully and to try to help nature rather than to make any definite attack on the disease itself. Rest, relief of pain and sleep should be obtained by morphine. Small doses of strychnine and alcohol provide the necessary stimulants when the heart lags. The ice-bag and cold sponges should of course be used. Oxygen is of value, if administered in time. Digitalin and nitroglycerin should be avoided, but saline infusions are of value in increasing diuresis.

BOOK REVIEWS.

Modern Microscopy. By M. I. Cross and Martin J. Cole. Third edition. W. T. Keener & Co., Chicago.

There is always an eager band of students to whom the mysteries of the microscope offer a most enticing field. Guides to the proper use of this book of nature are not many and we welcome all that promise to be of use to the searchers after the hidden secrets of organic life.

This is a handy and useful volume and can be thoroughly recommended to the student. How to use the microscope, how to mount, stain and present specimens, are all well told. We cordially grant it a place of honor on our laboratory table.

A Text-book of Legal Medicine and Toxicology. Edited by Frederick Peterson, M.D., Clinical Professor of Psychiatry, Columbia University, and Walter S. Haines, M.D., Professor of Chemistry, Pharmacy, and Toxicology in Rush Medical College. Vol. 2. W. B. Saunders & Company, Philadelphia, New York and London.

For a number of years this work has been anxiously awaited, as there has been a distinct need for a more authoritative and modern work on the subject than is possessed for the English reading public.

The time spent has not been wasted, for in these two volumes, taken in their entirety, we possess a thorough and modern encyclopedic handling of the subject-matters of legal medicine and toxicology.

We would like to have space to comment on some of the excellent features of this second volume, but beyond the expression of commendation for the entire volume we cannot stop to particularize.

Medical Jurisprudence. By Edwin Welles Dwight, M.D., Instructor in Legal Medicine, Harvard University. Lea Brothers & Co., New York and Philadelphia.

We do not know of a similar quiz compend on this subject that adapts itself so thoroughly to the needs of the average student as this.

As a rule it takes many years in practice before one exhausts, as it were, the simple questions that are here treated, and each one in its turn comes up in an unexpected manner and ofttimes the ingenuity of the physician is severely taxed in adapting himself to the unfamiliar medicolegal relationships.

Death, presumption of, survivorship, identification of the dead, causes of sudden death, medicolegal aspects of pregnancy, abortion and divorce, infanticide, legitimacy, insanity, life insurance, etc., are among the topics discussed. For a handy and ready work of reference this small epitome is a much appreciated help. We commend it cordially to beginners.

ORIGINAL ARTICLES.

THE SYMPTOMATOLOGY, DIFFERENTIAL DIAGNOSIS AND COURSE OF BRONCHOPNEUMONIA IN CHILDREN.*

BY MATTHIAS NICOLL, JR., M.D.,

OF NEW YORK;

ATTENDING PHYSICIAN WILLARD PARKER AND RIVERSIDE HOSPITALS; ATTENDING PHYSICIAN DEPARTMENT OF CHILDREN'S DISEASES, BELLEVUE HOSPITAL, OUT-PATIENT DEPARTMENT; INSTRUCTOR IN PEDIATRICS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; PATHOLOGIST NEW YORK FOUNDLING HOSPITAL.

IN presenting these observations on the most frequent disease of infancy and early childhood, I do so, not in the hope of adding anything that is novel to the knowledge of the subject, but principally in order to set boundaries, as well-defined as may be, about the discussion that is to follow. For which reason I may be excused for dwelling somewhat at length on a working definition, or rather description of bronchopneumonia.

Three varieties of pneumonia, exclusive of tuberculosis, are commonly met with at autopsies on children, representing, as it seems to me, three powers of resistance to the invasion of the pulmonary structure by pathogenic organisms. First, hypostatic pneumonia, the pneumonia of the least resistant of the marantic, those wasted by long-continued disease, the pneumonia of the weakening heart. Second, bronchopneumonia, the pneumonia of the more resistant child, who is, however, still physically handicapped by reason of age, surroundings, bad air, improper food and previous illness. Third, lobar pneumonia, the pneumonia of the most resistant, of the child usually over three years of age, in previously robust health, non-catarrhal, non-rachitic, infrequently a tenement-house dweller, rarely an inhabitant of an institution, the primary benign pneumonia of so-called good private practice.

With the first variety we have nothing to do; it represents but the final stage in a feeble struggle for life, long destined to be futile. It is rarely of importance clinically, and infrequently diagnosticated during life. The third variety, lobar pneumonia, received ample attention at our last session, somewhat at the expense of the more important disease.

Bronchopneumonia is essentially a disease of the poor and unfortunate. It must be studied in great part in dispensaries, tenement houses and infant asylums. In the latter, especially when coming in the wake of epidemics of the various infectious diseases, it constitutes a veritable scourge.

While it is undoubtedly true that the child of the institution and tenement is somewhat more frequently exposed to the action of the micro-organisms which are the cause of this disease, yet when we consider how omnipresent are these same organisms at certain seasons of the year, this fact alone cannot be held accountable for the immense preponderance of cases of bronchopneumonia occurring amid these surroundings.

It is not in the germ, but the character of the tissues upon which it is implanted, that we must seek an explanation of this fact. What are the factors which go to render a child susceptible to bronchopneumonia? Briefly they are, insufficient fresh air and sunlight, improper food, or food not adapted to individual needs; unsuitable clothing; health impaired by previous illness, and lack of attention to pathological conditions of the upper air passages. These factors, wholly or in part, are present even in the best conducted institutions, and in all tenement houses. The results are rachitis, anemia, chronic nasopharyngeal catarrh, and chronic gastro-intestinal disturbances, which collectively serve to distinguish the ready victim of bronchopneumonia.

For the purposes of this discussion I have analyzed somewhat carefully 167 cases of so-called primary bronchopneumonia, believing that the clinical picture in primary cases is more characteristic than in those which are classed as secondary. They occurred at the New York Foundling Hospital during the past three years, and in no instance were complications of one of the exanthemata, diphtheria or whooping-cough. What proportion was due to influenza it is not possible to say, nor is it always easy to determine whether the severe enteric symptoms of some of the cases were an indirect cause or result of the pulmonary lesion. Many developed outside of the institution to which they were brought by their foster mothers, generally from tenements, for hospital treatment. Of these the histories are necessarily defective. The number analyzed represents but a fraction of the cases of bronchopneumonia actually occurring at this institution during this time, the great majority being classed as complications of the infectious exanthemata, diphtheria or whooping-cough, or only appearing upon the autopsy records, the pulmonary lesions not having been noted during life, or deemed of insufficient clinical importance, in the presence of the overshadowing primary disease, to merit special mention in the clinical records.

It must not be forgotten that it is exceptional at this institution to find at autopsy, lungs which are free from pneumonic lesions, for which reason it would obviously be absurd to class all cases in which these are found as those of bronchopneumonia.

While the number of cases analyzed is a somewhat small one from which to draw general con-

* Read before the Pediatric Section of the New York Academy of Medicine, Jan. 14, 1904.

clusions, as the deductions correspond very closely to those drawn from a much greater number, they are of value as showing the conditions existing in institutions at present, and during the immediate past.

Bronchopneumonia is essentially a secondary or complicating disease. One-third of the cases are generally set down as primary, a proportion which would seem a good deal too large, in so far, at least, as it relates to institutions. In the latter, the milder catarrhal affections of the upper air passages are generally overlooked; acute coryza, tracheitis, and even bronchitis of the larger tubes and mild influenza does not, in my experience, call for especial attention from a resident physician or nurse, provided the patient is not particularly ill, the consequence is that when the child is first examined, the signs of pneumonia are often well developed, and if they have not followed one of the severe, acute, infectious diseases, the case is classed as primary. If more careful observations were made upon institution children, from the time they developed a so-called "cold" with fever, the number of cases of bronchopneumonia, which are now classed as primary, would be materially reduced.

Occurrence.—Bronchopneumonia, unlike lobar pneumonia, occurs at all seasons of the year; thus in the list of cases referred to, somewhat less than one-third occurred in both winter and spring, about one-fourth in the fall, and about one-eighth in the summer quarter, or two-thirds of the cases between December and May. Males are somewhat more frequently attacked than females, 96 to 71, about five to four. As there is a slight preponderance of males at the Foundling Hospital, the fact is not noteworthy, although this is the proportion usually given, and is difficult to account for.

Of 147 cases in which the age was stated, over 58 per cent. occurred in children under one year of age; 20 per cent. from the first to the second year; 13 per cent. from the second to the third year; and 9 per cent. in those over three and under five. In other words, 70 per cent. of the cases were in children under two years of age.

Causes.—The indirect causes have been sufficiently indicated. The direct causes are exposure to cold, extension of an inflammation from the upper air passages downward, the acute infectious diseases, diarrheal diseases, or any factor which still further diminishes the feeble resisting power of the child to pulmonary organisms.

Symptoms.—There is no disease more irregular in its course and uncertain in its outcome than bronchopneumonia, on account of the variety of bacteria which either singly, but much more often in combination, are responsible for the pulmonary lesion and also to the varying amount of lung involved, and the greater or less resistance shown by the patient to the action of the toxins.

There is often a history of previous good health, or of acute catarrhal trouble of the upper air passages, moderate or severe bronchitis, convalescence from an acute infectious disease, or exposure to cold. Whether the pneumonia develops during the course of an acute infectious disease, in convalescence from it, or while the child is in its usual state of health, the onset is invariably sudden, and is ushered in in one of several ways; the child becomes apathetic, ceases to play, refuses to nurse properly, or is irritable and restless. Vomiting occurred six times in 56 cases of which I could obtain the history of onset; convulsions in five; chills were noted in two cases; there is generally more or less cough, and the bowel movements are frequently loose and green in color; the skin is hot, the respirations are increased in frequency, the pulse is rapid; the child when disturbed does not cry in a normal way; the cry is curtailed and ends abruptly, as though the expiratory effort caused pain or discomfort; the rhythm of respiration is disturbed; the pause which in health occurs after expiration is lost, and instead occurs after inspiration; the child inspires, holds its breath, and lets it out with a characteristic grunt, and immediately inspires again, possibly another indication that expiratory effort causes discomfort or pain.

Physical Examination.—The temperature will be found elevated four or five degrees or more, the respirations forty or more to the minute, the pulse 120 or over, the ratio of the respiration to the pulse, which in health is one to four, invariably approaches one to three, or less, or even one to two; in the more severe cases there is marked retraction at the epigastrium and about the clavicles, the alæ nasi expand and there may be more or less cyanosis seen in the lips and finger tips; the face is sometimes flushed, often pale.

On palpation the coarse râles of bronchitis are transmitted to the touch, or the cry may show unequal intensity of transmission on the two sides, especially at the bases or apices.

Percussion, which should be performed very lightly, the stroke sharp and quick, is of minor diagnostic importance in the early stages of the disease. Dulness may be elicited when there is marked congestion at the bases, or when the areas of consolidation involve a greater part of a lobe.

Auscultation is by far the most important factor in arriving at a diagnosis in the early stages. With the presence of a general bronchitis, coarse, moist râles are heard over a greater part of the chest, or only between the scapulæ and below the clavicles. Subcrepitant and fine râles, emanating from the finer bronchi and air vesicles, should be diligently sought for, as taken in connection with the symptoms described, they are conclusive proof of involvement of the terminal bronchi or air vesicles, or of pulmonary congestion. They may be very generally distributed, but are more often heard only over small areas, at one or both bases near the spine, in the axillæ, or at the apices. They may be heard constantly, or only when the child is induced to take a deep inspiration, as after crying, or an attack of coughing. Early in the disease there is usually no change in the character of the respiratory sounds. Over areas of consolidation of considerable extent

there may be exaggerated, diminished, or bronchovesicular breathing, the latter distant or intense, depending upon the proximity of the area to the chest wall, the condition of the lung overlying it, whether or not emphysematous, and the presence or absence of pleuritic involvement.

Finally, it must not be forgotten that considerable areas of consolidation may be found at autopsy, of which, during life, there was no evidence other than the presence of a few râles, and even these may have been absent. The physical signs may all be delayed for several days, or may be entirely absent during the whole course of the illness. Again, it not infrequently happens that the signs of consolidation are first recognized just before defervescence takes place.

Course of the Disease.—In the typical cases the fever rises rapidly to 104° F. or over, and continues with morning remissions of two or three degrees for a variable number of days. In my list of cases the average duration in those that recovered was thirteen to fourteen days; in five cases four days or less; it may continue for one or two months with the development of chronic changes in the lungs; in children of low vitality the disease may run its course practically without fever; and again the remissions of temperature may be very marked. The latter is especially true of cases in which the influence of the streptococcus predominates; in cases which recover the general trend of the temperature is downward after two or three days; in fatal cases the temperature of each day is a little higher than that of the preceding, the highest point being reached just before death, or it may rise suddenly to 106° or 108° F., and death take place in twelve to twenty-four hours; the fever falls by a more or less gradual lysis, exceptionally by crisis, which occurred but nine times in 167 cases.

The pulse is at first rapid and of good force; later in the disease rapid and feeble; as already stated, it constantly bears a ratio to the respiration of three to one, or less. The character of the respirations has been described; they vary in frequency from 40 to 100 or more a minute; they may occasionally be suspended for a considerable time, or be of the Cheyne-Stokes variety.

Cough may be entirely absent, it is often persistent and nagging; generally dry in character, or a large amount of mucus may be raised and swallowed. Suppression of the cough is seen in fatal cases.

Vomiting, after the disease has once begun is not frequently seen; on the other hand, the bowels as a rule show evidence of disturbed digestion; the movements are frequent, green in color, and contain more or less mucus. Catarrhal conditions of the enteric tract are common, especially in the cases occurring in the summer months. Gaseous distention of the intestines is often seen and may be so severe as to seriously interfere with the already embarrassed respiration.

Nervous System.—Stiffness of the neck and shoulders is marked in many epidemics; there may be intermittent spasm in groups of muscles. Delirium occurs in older children, convulsions after the first onset, usually only in the rachitic and in fatal cases. The tâche cérébrale and Kernig's sign are occasionally seen.

It is unnecessary to dwell at length on the symptoms of those cases which arise in the course of the acute infectious diseases. But for the fact that they are often obscured by the symptoms of the primary disease and of their usually greater severity, they do not differ essentially from those just described.

Diagnosis.—When a child under three years of age becomes suddenly and gravely ill, bronchopneumonia should always be thought of, even if the symptoms referable to other organs, as the brain and intestines, serve to draw the attention from the lungs; or if in the course of convalescence from an acute infectious disease, the temperature is suddenly elevated, the pulse and respiration increased in frequency, bronchopneumonia is by far the most probable cause.

The diagnosis is based on the acute onset in primary cases, the aggravation of all symptoms in secondary cases; in primary cases on the changed demeanor of the child and evidence of toxemia, fever continued over thirty-six hours with increase of respiration and pulse, and most important of all, the disturbance of the respiration, pulse ratio and the presence of fine râles, especially if localized, and occasionally a change in the respiratory sounds. Cough is not an essential.

Differential Diagnosis.—Fever in a young child occurs alone in so many conditions that it is of little diagnostic value; fever with respiration over 40 to the minute, and with a diminished ratio between it and the pulse rate occurs in other conditions than bronchopneumonia, but is rarely long continued except in the latter. It is seen in digestive disturbances with intestinal distention, at the onset of acute infectious diseases, especially when these are accompanied by involvement of the air passages; thus in measles, during the height of the fever, disturbance of the respiration pulse ratio is the rule. Scarlet fever, on the other hand, rarely gives it; acute bronchitis, meningitis, nasal obstruction due to acute nasopharyngeal infection, laryngeal stenosis, and, finally, it is probable certain reflexes, as those due to dentition, middle-ear and mastoid diseases, may be a cause of this common phenomenon.

Bronchopneumonia may be distinguished from bronchitis of the large and medium bronchi by the lower temperature and shorter course of the latter, usually not over four or five days, absence of toxemia, and of the characteristic râles of bronchopneumonia.

From so-called capillary bronchitis it is not possible nor essential to distinguish bronchopneumonia; the cases of the former, in which I have had an opportunity to make a microscopic examination of the lung, invariably showed more or less involvement of the air vesicles. There seems to be no good reason for making a clinical

distinction between a disseminated bronchopneumonia and a capillary bronchitis.

Fluid in the chest in infants and young children, usually occurs as a complication or sequela of pneumonia, either of the bronchial or lobar type. It is more often turbid in character or a thick, creamy pus than clear serum. The cases of bronchopneumonia in which it is found are usually those in which there is involvement of the greater part of one lower lobe. There may be a bulging of the chest wall on the affected side and more or less displacement of the heart to the opposite side, percussion will give dulness or flatness over one of the bases, extending well up in the axillary line; on auscultation there is diminished or absence of breathing on the affected side and with an underlying bronchopneumonia or compressed long distal bronchial breathing. Pleuritic râles are frequently heard. Finally, in cases of doubt, exploratory puncture should be made with a needle of large caliber.

Bronchopneumonia is sometimes mistaken for laryngeal stenosis by those unfamiliar with the symptoms of the latter, and I am informed by an antitoxin inspector of the Board of Health that in his experience, cases of the former are occasionally intubated by mistake. The comparatively slow, painful and perfectly characteristic respiration of laryngeal stenosis, marked epigastric and sternal recession, the expression of intense anxiety or even terror on the face of the child, all constitute a picture which is so typical that it would seem that only lack of experience could justify its being mistaken for any other condition.

When bronchopneumonia occurs in the course of a laryngeal diphtheria, its recognition by physical examination is sometimes rendered difficult by the transmission of the abnormal respiratory sounds from larynx and trachea, so that the diagnosis must be made largely on the symptoms (rise in fever, respiration and pulse). When pneumonia is present in such cases, the question sometimes arises if the appearance of a marked cyanosis, dyspnea and air hunger is due more to the complicating pneumonia or laryngeal condition; in desperate cases, when the question cannot be definitely settled, it is perfectly justifiable to exclude the laryngeal element by the performance of intubation.

Meningitis of any variety should not be mistaken for pneumonia; on the other hand, bronchopneumonia, with exaggerated nervous phenomena, may at its onset lead to an erroneous diagnosis of meningitis. Both diseases may be ushered in by convulsions, which may recur repeatedly during the course of the disease. In both there may be spasm of groups of muscles together with ocular symptoms; in both Kernig's sign and tâche cérébrale may be found; rigidity of the neck is not uncommon in pneumonia, while the apathetic facial expression of the latter bears somewhat of a resemblance to the mask-like face of meningitis. Finally Cheyne-Stokes respiration may occur in both. The respiration of meningitis is slow, characteristic of the disease and usually quite unlike that of pneumonia. The pulse is slow or not markedly quickened and is irregular; the rigidity of the neck is much more marked; opisthotonos is frequently present; muscular spasms are much more lasting; ocular symptoms occur with great regularity together with paralyses, coma and delirium. Finally, in cases which cannot be otherwise differentiated, lumbar puncture will generally accomplish the result.

Malaria, especially when, as is frequently the case, it is accompanied by bronchitis, may be mistaken for bronchopneumonia; enlargement of the spleen does not serve to render a positive differential diagnosis and blood examination must be relied on in doubtful cases.

I have only to add that in obscure, acute, febrile cases occurring in young children, the possibility of bronchopneumonia must never be overlooked, and the practitioner who has the various phases of this protean disease constantly before his mind can alone hope to avoid pitfalls laid for the unwary; even though, in accomplishing this end he becomes a species of devil's advocate, coming to regard every suspicious case as guilty until proven innocent.

124 East Sixtieth Street.

THE PATHOLOGY OF LOBAR AND BRONCHOPNEUMONIA IN INFANTS AND CHILDREN.*

BY DAVID BOVAIRD, JR., M.D.,
OF NEW YORK.

While there may be room for differences of opinion as to the relative frequency of lobar and bronchopneumonia among infants and children in clinical experience, there is no doubt as to the prevalence of the latter affection in the autopsy room. In the last 500 autopsies at the Foundling Hospital we find bronchopneumonia recorded 191 times, approximately 40 per cent of the examinations, while lobar pneumonia was found in but 25 cases, 2 per cent. of the examinations. These figures throw no light on the question of the relative frequency of the two affections during life. In the early years of life lobar pneumonia is regularly a primary disease, is rarely fatal and is therefore infrequent in the autopsy room. Bronchopneumonia, on the other hand, is rarely primary, but is the dreaded complication of the infectious diseases so common among children, especially measles, diphtheria, whooping cough and the gastro-intestinal affections. Attacking patients already weakened it is correspondingly more fatal and more frequently seen in the post-mortem examinations.

The pathology of lobar pneumonia in infants and children presents no striking differences from the appearances familiar in later life. So far as my personal experience is concerned I cannot recall ever having seen in the infant or child the primary state of lobar pneumonia, that is the stage

* Read before the Pediatric Section of the Academy of Medicine, New York, Dec. 10, 1903.

of simple congestion. We regularly find it as a red or gray hepatization of one or more lobes of one or both lungs. Of the 25 fatal cases already mentioned 12 involved the right lung, 6 the left, and in 7 instances both lungs were affected. In the stage of hepatization the affected lobe or lobes is enlarged, firm, the pleural surface injected and hazy or rough from a coating of fibrin, and on section the lung is airless, granular, deep red or grayish red. While there may be shadings in the color of the exposed surface, one part being redder than another, the section is usually quite uniform, a characteristic which taken in connection with the granular appearance is fairly distinctive of the lobar type of inflammation.

While, as a rule, a whole lobe or several lobes are involved in the process, it is more common in children than adults to see a partial consolidation of a lobe, or a distinctly lobular type of pneumonia. Apart from the question of the area involved the appearances are the same.

The amount of pleurisy seen in these cases varies greatly. Most frequently there is only enough fibrinous exudation to render the pleura hazy or slightly granular, but it is not uncommon to see a heavy deposit, pale greenish-white or yellow in color, plastered like a mortar over the pleura to the depth of one-third to one-half inch. There are all grades between these two extremes. With the pleurisy there will be more or less serum, sero-pus, or pus in the pleural space. In some cases of lobar pneumonia the infiltration of the lung is so intense and the degeneration of the cells so advanced as to give a very granular appearance and a pale yellowish color to the cut surface very suggestive of the caseous pneumonia more often seen in adults. One instance of this kind I recall in which two very competent pathologists regarded the process as surely tuberculous, but smears from the surface showed an abundance of pneumococci and no tubercle bacilli.

As a very great rarity true caseous pneumonia may occur in infancy. The one example of this process which I have seen closely resembled the ordinary lobar pneumonia, but the affected lung was more dense, the cut surface was more granular and more uniformly yellowish-white than in the common consolidation. Smears from the surface showed numbers of tubercle bacilli. From time to time small abscesses may be seen in the consolidation of lobar pneumonia, and more or less extensive gangrene of the lung may occur.

The microscopical picture in lobar pneumonia is fairly familiar. The pleural surface shows the fibrinous exudate, the air spaces and the smaller bronchi are filled with an exudate of red blood cells, leucocytes, epithelium, and fibrin, together with bacteria. In the early stages the congestion is marked and there will be abundance of blood in the exudation. Later the blood disappears and the other elements of the exudate increase. There is usually less epithelial desquamation but more fibrin, and the fibrin is more uniformly distributed through the section. The general connective tissue of the lung is swollen and may show some infiltration with new cells. If abscesses are formed or gangrene develops, the corresponding appearances will be seen in the section.

Apart from the pleurisy regularly met with in lobar pneumonia the most important associated lesions are the inflammations of the other serous membrane, the pericardium, the meninges, and the peritoneum. In these tissues we may see a serofibrinous inflammation, and especially in the pericardium or the meninges the deposit of fibrin may be very heavy. Such complicating processes are regularly due to the activities of the pneumococcus and are the evidence of a general infection with that organism.

With the appearance of bronchopneumonia in infancy and childhood we are much more familiar. As already stated the complicating pneumonia of the infectious diseases is regularly of the bronchial type, and bronchopneumonia is met with in about 40 per cent. of all the autopsies at the Foundling Hospital.

In general three distinct types of bronchopneumonia are recognized, types which represent stages in the development of the process, just as the congestion, red hepatization and gray hepatization represent the stages in the evolution of lobar pneumonia. In all three stages the process is regularly bilateral, and for the most part symmetrical. The posterior parts of the lungs usually show more extensive consolidation than the anterior, although it is not at all infrequent to find the anterior extremities of the upper lobes firmly consolidated. In the first of these stages or types, the beginning bronchopneumonia or the capillary bronchitis of former years, the surface of the lung may appear normal or there may be a few small areas of collapse, the affected portions being deep blue, depressed, and airless. On section the greater portion of the lung appears normal, but about the smaller bronchi there are throughout both lungs rings of deep red congestion, and on opening the bronchi the appearances of a bronchitis are found. In such cases it may be quite impossible to appreciate by sight or touch the presence of any consolidation, but on microscopical examination we find the smaller bronchi full of an exudation, consisting of epithelium from its walls and leucocytes, together with bacteria. The wall of the bronchus appears swollen, is infiltrated with leucocytes, which may be observed between the cells still affixed to the wall, in the submucosa and beneath it. The air-cells immediately about the bronchus will be found filled with cells exfoliated from their walls, with leucocytes and a very little fibrin. In some cases we see many red blood cells, but this is quite unusual. At the periphery of the zone of inflammation will be seen a ring of air-cells in which the exudation is very largely fibrin. In some instances the contents of the bronchi consist only of a fine glandular material and fragments of nuclei, and exudate having undergone necrosis.

The second stage or type shows areas of consolidation disseminated throughout the lung. The areas are of varying size, large enough to be ap-

preciated by the sense of touch as consolidations, and yet with lung tissue between them which is normal or congested or emphysematous. On section the surface is deep red, rather smooth and shiny, lacking the granular appearance so characteristic of the lobar consolidation. The smaller bronchi in these cases usually project slightly from the cut surface and, upon pressure, show plugs of muco-pus. The microscopical picture is essentially that already described, but involving more extensive areas.

The third stage is that known as pseudolobar bronchopneumonia, in which the previously disseminated areas of consolidation merge one into the other and a whole lobe becomes solid. The affected portions are airless, the cut surface may be slightly dull, but has not the granular look seen in the lobar pneumonia, and is almost always mottled or dappled dark red and gray, the lighter colored areas being the earlier and more intense peribronchial consolidation. Owing to the branching of the bronchi these lighter areas usually show something of a stellate arrangement, the figures formed suggesting the trefoil of the clover leaf. It is not at all uncommon to find in these extensive bronchopneumonias a breaking down of the smaller bronchi with the formation of small abscesses, and gangrene may occur, particularly in the bronchopneumonias associated with such processes as cancrum oris and diphtheria.

When a bronchopneumonia involves a whole lobe, we usually find that the posterior parts are much deeper in color than the anterior, owing to the attendant congestion; in fact, in the extensive consolidations seen in fatal cases of diphtheria and similar affections, we are often struck by the dirty-white color of the anterior portions of the upper lobes, although they are consolidated. Even in these paler areas the contrast between the peribronchial infiltration and the more peripheral consolidation can be appreciated. In most of the extensive bronchopneumonias there is considerable emphysema of the interstitial tissue in the anterior parts of the lungs.

With a bronchopneumonia involving the greater part of a lobe there is usually some pleurisy. As in the case of a lobar pneumonia there may be only a slight deposit of fibrin on the pleural surface or the exudate may be quite heavy. The very thick exudates are, however, more common in the lobar pneumonias. The writer has been impressed by the frequency with which empyema is associated with empyema. In a study of the pathology of empyema in infants the writer found that among 101 cases there was more or less consolidation of the lung in 56. Of these 56 cases 10 showed lobar pneumonia, 27 bronchopneumonia, 15 were indefinite, and 4 showed tuberculosis. This frequency of bronchopneumonia in association with empyema is, I believe, rather in contrast with the findings in the later years of life.

The microscopical picture in these extensive bronchopneumonias is only a more extensive development of the condition found in the early stages. The essential features are the infiltration of the walls of the smaller bronchi and the air-cells immediately about them, the abundant desquamation from the walls of the alveoli, the usually scanty appearance of red cells in the air-spaces and the smaller amount of fibrin in the exudate. With the development of abscesses or gangrene the corresponding appearances will be found in the section.

The bacteriology of lobar pneumonia is now well established. While other organisms may, under favorable conditions, cause such a pneumonia, in the great majority of cases (95 per cent Aufrecht) the *Micrococcus lanceolatus* or the pneumococcus is the causative agent. The pneumococcus may be found alone or associated with other organisms, the Friedländer bacillus, streptococci, staphylococci, and various others. The relation of the pneumococcus to lobar pneumonia has been strengthened by the demonstration of its presence in the blood in these cases. The workers of recent years have reported steadily increasing percentages of such blood infections. The Klemperer brothers never found the pneumococcus in the blood. Aufrecht says that they are found in the blood in from 10 per cent to 50 per cent of the cases. Silvestrini and Sertoli found them in 15 out of 16 cases. Prochaska, in 1901, reported 50 examinations with positive results in all. Rosenow, who gives a careful review of the whole subject, reports this year 77 positive results in 83 cases. All of which serves to more firmly establish the relation of the pneumococcus to the lobar pneumonia and to support the view that the affection is to be regarded as a general infection with a local lesion.

The bacteriology of bronchopneumonia is more complicated, but here again the pneumococcus is the prevalent organism, occurring in 50 per cent or more of the cases. In other instances streptococci, staphylococci, the Friedländer bacillus, the diphtheria bacillus (Frosch, Babes, Baginsky), the typhoid bacillus (Polynieri) may be found. The majority of the cases are mixed infections. In the primary cases the pneumococcus is more likely to be found. In the secondary cases the streptococci, staphylococci, the Friedländer bacillus, or the organism of the primary disease (diphtheria, typhoid, etc). Whether or not there is a blood infection in the primary cases of bronchopneumonia has not yet, to my knowledge, been proven. That such will be found to be the case seems highly probable, and we are very likely to arrive at a conception of the disease similar to that entertained for the lobar affection. The tendency of the present time seems to lead to the diminution of the importance attached to the local lesion and to the increased importance of the nature of the infecting organism and of the powers of resistance of the infected individual.

Typhoid in Paris.—In 1882 the deaths from typhoid fever in Paris were 142 per 100,000 inhabitants; to-day the proportion is only 10 per 100,000.

TREATMENT OF BRONCHOPNEUMONIA IN CHILDREN.*

BY W. P. NORTHRUP, M.D.,
OF NEW YORK;
PROFESSOR OF PEDIATRICS, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

What are we to treat, a lesion, or a patient with lesions?

Pulmonary inflammation in a child under three years is commonly bronchopneumonia because of anatomical peculiarities, among which may be mentioned much loose connective tissue, abundant lymph spaces, transitional (young, embryonal) cells, and, of course abundant blood vessels and unstable nerve centers. Given young tissue, mixed infection of pus-forming cocci, varying in virulence and rapidity of growth, in a subject exhausted by a previous disease, and we have all the elements to account for the irregularities of onset, course, ending and pathological findings. At autopsy we find masses in one lobe, or scattered masses in all lobes or a whole organ soggy and dripping with seropurulent exudate.

This is what we are to treat then—a case, or a patient with a pulmonary apparatus which is more or less in a condition of a pulmonary erysipelas or pulmonary cellulitis, with associated severe prostration, bacteriemia, septicemia. I believe we will make some progress in our conception of the disease, and in our rational treatment, if we think of bronchopneumonia as a pulmonary cellulitis, or a pulmonary erysipelas.

Bronchopneumonia is characterized by irregularities. It is commonly a secondary disease, incited by mixed infection, all the elements of the lung being, to a variable degree involved. The prognosis of the patient is uncertain because the child is twice a patient, exhausted by a second disease.

That household bogy—"catching cold" is less feared than formerly in connection with vaccination wounds, sprained ankle and erysipelas. This is a favorable time to think of bronchopneumonia as an infectious disease with active febrile movement. At present it is almost needful to withhold the name pneumonia from the parents; in order to do justice to the patient. Happily, at this date, in the progress of time and medicine, we no longer think a typhoid patient has caught cold if he develop bronchitis or that a facial erysipelas patient has suffered from a draught of air, if he adds empyema to his ailments. Mastoiditis does not cause the physician to be accused of needlessly exposing a scarlet patient. The poor doctor is always to be blamed, but he has promise of some relief; sometime the blame will be thrown upon the patient, his run down condition and his germ.

Who can forget Alonzo Clark's courageous act in letting air into the typhus wards? To-day a typhus in a tent would not excite a remark.

Prophylactic Treatment.—I shall mention but one, antitoxin—that is the immunization of diseases liable to diphtheria complications, in institution epidemics. This may apply to the crowding of measles patients especially. No physician can longer afford the opprobrium of the bad results following the omission of this precaution, even if it be possible that he is congenitally deficient, either in medical judgment or conscience. Immunizing measles cases when grouped, prevents the complications of diphtheria and much of the subsequent pneumonia.

I shall not take the time of this audience to drone over the prescriptions for pneumonia in infants. I shall give only my own ideas of treating a patient whose pulmonary tissues are, every element of them, stroma, cells, lymphatis and blood vessels reacting to overcome the deleterious effects of various growing, pus-forming cocci. We are told by the blood students and pathologists of a struggle of body cells and serum against cocci and toxins, of homemade antitoxins, and a shadowy suggestion of a kind curing Nature. I mean to dwell upon hygienic aids, and this not being a cyclopedic paper or audience, I may not be blamed if I omit drugs. The walls of this Academy know very well that drugs have had their innings.

TREATMENT.

How shall we help a patient with bronchopneumonia to get well? How give Nature a fair field for the struggle? In preparing this paper I have drawn upon the experience of several years. The problem is how to sustain the patient in overcoming the toxemia, the manifestations being fever, stupor, restlessness, delirium, disturbed circulation, heart fatigue and persistent cough.

Hygienic Treatment.—1. Fresh air, preferably a large room, southern exposure, sun swept; bed in middle of room, eyes directed away from bright light. Air should be fresh, cool and flowing. Temperature below 65° F. Nurses may need extra wraps. Flowing and fresh mean the same. A child with a lame lung should not breathe five times when three times will do. With limited capacity the lung demands oxygen in the natural proportions to be found in the atmosphere. The above conditions apply to a child in sthenic febrile reaction.

How about "catching cold?" In my opinion such a patient is no more liable to catch cold than a case of erysipelas of the face or leg, no more than a scarlet fever patient in its early sthenic reaction to poison. The freshly liberated poison in a patient capable of bounding reaction, summons into response all of Nature's resources of protection, and acts as a sharp stimulant.

You may recall the story of the burning of a pneumonia hospital in the mountains of Western Virginia, in war times. A sharp snowstorm and exposure of overtired soldiers, brought down a large number of pneumonias. Overtaxed heating apparatus burned up the hospital. There was a wail reiterated through the papers of the land, that all these unfortunate soldiers must die because they were lying in the snow, with only a canvas stretched over barrels to protect them. They all got well.

* Read before the Pediatric Section, New York Academy of Medicine, January 14, 1904.

No one catches cold from fresh air entering the nostrils or from fresh, cool, flowing air striking the oval of the face. An overworked débutante, emerging from a hot theater, with her face puffed and dusky from a blood full of second-hand breaths, may catch cold because her defenses are down and she easily succumbs, but I have never any fear of a fever patient catching cold in bed.

2. Water, plenty of it in small quantities, cool and fresh. It both refreshes and facilitates natural elimination. I intend to reiterate the word "refresh" in the treatment of pneumonia. Refresh the patient with cool, fresh air. Refresh with water, and plenty of both.

3. Quiet and rest. The one thing in treatment easily forgotten is tranquillity and restfulness. Pneumonia patients are nervously susceptible to noise and confusion and worn out by it. A tearful grandmother should be removed. A single trained nurse of congenial temperament should be in sole charge. The sickroom should not be the gathering room of the clan; Sunday afternoons should not find the door of the patient's room ajar to every pusher and to every push. But yesterday I was obliged to clear a room of two old women, four big sons and a pug dog, leaving two doctors, a patient and a nurse.

4. Free evacuation of the bowels at the very outset. This should be effected by castor oil in full doses, with or without previous calomel. Never give anything but full doses of castor oil, full for the age. Good cleansing of the intestinal tract is the first aid to the injured. Something seems to happen to the intestinal contents at the first moment of the febrile onset. It thenceforth appears to contain an absorbable poison, the removal of which often allows the fever to fall abruptly. If the fever rises subsequently, in spite of elimination, the diagnosis and course of treatment are clear.

5. Correct indigestion; regulate the food to avoid fermentations and gas. This is often the most troublesome feature of a case. Avoid cough syrups and fermentable foods. The pressure upon heart and lungs by a gas-filled stomach and colon does not leave a fair field to nature. To correct this condition, when present, high rectal irrigations of a hot salt solution act favorably.

6. Antipyretics. Make use of sponging or cold applications of water administered in any way to reduce temperature without disturbing or worrying the child. But remember it is possible to do harm in this way, often more harm than good. Just here let me say, that if every clinical thermometer should fall to the tile floors with a crash, to-night, though all other cases might suffer, not a pneumonia case would. That ever-present, blessed thermometer, like a stepmother, may be bad, or a misfit. Our students are drilled to begin something the moment the thermometer points to 102.5° F. They generally begin to move at 102.5° F. before they can remember which disease it is requires antipyretics.

To judge of a pneumonic child stand at the foot of the bed ten minutes, watch and think. Take your stethoscope and leave the thermometer and prescription book in the bureau drawer at home. One other point; try by example and precept, line upon line, to drill it into the minds of nurses to take some observations besides those recorded on the thermometer. It is a fault in our nurses' training that they never take the respiration of an infant or child. They always take the temperature, sometimes the pulse, but never the respiration. The consequence is that the physician usually has to do that himself. It is the toxemic symptoms, fever, stupor, restlessness and delirium, which suggests the line of treatment. What the thermometer reads is of very little consequence. Different patients bear temperature variously.

An ice cap to the head: Well, to put it into words, we usually apply ice caps to the hair. A polar bear takes his nap after lunch most comfortably on an iceberg. He simply curls up in his hair, on his ice cap, and dreams of honey and grapes. Hair is so poor a conductor of heat, the scalp must often wish it were bald. A cloth wrung out in cold or cool water and applied to the forehead and temples, with frequent sponging of the face, wetting of the lips and sponging of hands and wrists, accomplishes much. It refreshes and cools.

7. Heart stimulation is not always needed. I have come to think that when a heart is acting badly in pneumonia, it is time to see how much gas is in the abdomen, how clammy and cold the feet are, how hot the head. I tell a nurse to quit recording temperature, to take the respiration and the pulse, but every time she takes temperature, to take the toes; in other words, to see if the feet are cold. A child with cold feet cannot digest. Gas forms, the heart cannot find room to beat regularly. It makes me *think* something to find a nurse reporting an intermittent pulse and giving heart stimulants, and on arrival I find the patient's feet and hands are cold and clammy. Hot foot-baths cure that kind of heart trouble. Give the foot-baths with or without mustard. It's the *heat* we want, heat sufficient to puff the feet, red and hot and swollen with blood which had made up its mind to go elsewhere. Give the foot-bath under the bed clothes. I never saw a Junnaud's boot, but as I understand it, it was one grand cupping glass to draw the blood into one leg. I approve of that part of it. To stimulate the heart, relieve its embarrassment by hot, high salines and hot foot-baths.

8. Promote general comfort. This most important aid calls for tranquillity of surroundings, sponging the face, wetting the lips, not too frequent dosing and feeding and allowing long sleeps, and the employment of congenial, tactful nurses.

Things to Avoid.—Avoid all constriction of the chest; swathing poultices. Poultice for pain only.

Avoid maceration of the child's skin. Change to warmed dry garments often enough to avoid it. Keep patient comfortable.

Avoid disturbing the child's needed rest. When the critical sleep comes to a previously restless child, recognize it and do not disturb it.

Avoid steam and canopies. They are good in catarrhal laryngitis with spasmodic cough, but not for bronchopneumonia for they rob the patient of oxygen. The indications for foot-baths are: Restlessness, drowsiness, dusky, flushed face, and persistent, nagging cough. The results are quiet sleep, averaging two to four hours; prompt relief of cough, flush leaving the face in fifteen minutes, followed by sleep immediately thereafter. In fact, it is a result which is satisfactory and encouraging to physicians, nurses and parents. If all who witness the effect of treatment day by day, approve it, especially the parents of an only child, there is something good in it.

My contention is for fresh air, cool and flowing, for the full proportion of oxygen natural in the atmosphere. No secondhand breaths for lame lungs. Call the case pulmonary fever or pulmonary cellulitis, and treat it rationally. I have seen such favorable changes from removing a child from an inner sunless room to a room with two open windows, changes in color and in mental condition that I am sure I cannot be mistaken about the good result. I have seen the same good results in robust adults and in infants, and all ages and conditions between. Have I seen any bad result? No. I never saw anything but good in giving air and water to a fever patient. My impression is one cannot give too much. Our city houses are full of exhalations of human beings, permeated by furnace gas and escaping illuminating gas, full of dust, and overheated. A person overtired and worn out from loss of sleep is caught by cold.

To summarize how to cure a baby with bronchopneumonia.—1. Castor oil to clear the field of operation. It is the first aid to the injured.

2. Fresh air, cool and flowing. It reddens the blood, stimulates the heart, improves digestion, quiets restlessness, aids against toxemia. Regulate the temperature of air of the room inversely to that of the child. The patient's feet must always be warm, and the head cool.

3. Water, plenty, inside and outside. Temperature of the water as indicated by child's temperature.

4. Quiet and rest. Tranquilizing influences about patient. Undisturbed sleep.

5. Correct feedings to avoid fermentation and gas in abdomen. If there is need, high hot salines.

6. Antipyretics. Water. No coal-tar products.

7. Heart stimulants. Fresh air, hot foot-baths. Relieving tympanites and crowding. Hot foot-baths and hot salines can be given in a cold room. Both can be given under the bedclothes.

Drugs.—Whisky and strychnine. These are the first drugs mentioned in this paper, unless that household remedy, castor oil, be included. Promote general comfort in every rational way.

How to Kill a Baby with Pneumonia.—Crib in far corner of room with canopy over it. Steam kettle; gas stove (leaky tubing). Room at 80° F. Many gas jets burning. Friends in the room, also the pug dog. Chest tightly enveloped in waistcoat poultice. If child's temperature is 105° F. make a poultice thick, hot and tight. Blanket the windows, shut the doors. If these do not do it, give coal-tar antipyretics and wait.

THE BEHAVIOR OF THE COSTAL ARCH IN DISEASES OF THE ABDOMINAL ORGANS AND ITS IMPORTANCE AS A DIAGNOSTIC SYMPTOM.

BY ELLSWORTH ELIOT, JR., M.D.,
OF NEW YORK;
ATTENDING SURGEON, PRESBYTERIAN HOSPITAL, NEW YORK.

(Continued from Page 774.)

Case IX. Cholelithiasis in the Quiescent Stage.—M. K., aged forty-six years; admitted to the hospital December 11, 1901. Patient has always enjoyed excellent health until five months ago, when she suffered from an attack of dysentery lasting five to six weeks. Three months ago patient was seized with a severe attack of vomiting and of abdominal pain over the region of the gall-bladder, lasting for several days. There was slight jaundice and costive, slightly clay-colored stools. Since then the attacks have recurred every few days, their onset being favored by the ingestion of any form of solid food. During each attack she is prostrated and unable to attend to her household duties. The constipation is constant.

Examination on Admission.—Patient is very corpulent, with a large, pendulous abdomen. There is slight icterus. There is tenderness over the region of the gall-bladder. There is rigidity of the corresponding portion of the costal arch of moderate degree but no rigidity of the adjacent segment of the rectus muscle.

Operation (Gas and Ether).—An oblique incision, parallel to the lower border of the costal arch, was made, with its center over the region of the gall-bladder. This organ was found completely embedded in adhesions and of small size. It had been drawn nearly to the median line by the contraction of the tissue in which it was embedded, and was adherent to both the stomach and the under surface of the liver. The gastro-hepatic omentum was very considerably shortened, the lesser curvature of the stomach lying close to the under surface of the liver, and the foramen of Winslow obliterated. The gall-bladder was very atrophic, and its wall a thickened mass of connective tissue. It was opened and several small calculi and considerable calculus detritus was removed. Owing to the density of the adhesions, it could not be separated from the adjacent liver without undue risk of hemorrhage. A tampon of gauze was then inserted down to the orfice and into the cavity of the atrophic bladder, it being impossible to approximate it to the parietal peritoneum. Closure of the incision in layers on either side of the drain.

Postoperative.—The patient suffered intense pain for forty-eight hours, at the end of which time the biliary fistula became established. The vomiting was also persistent for three days, until the bowels moved. There was no distention. After the third day rapid improvement, the further convalescence being uneventful and the fistula completely closing in six weeks. December, 1902. Except for slight rheumatic pains, patient has had excellent health since the operation.

Case X. "Perihepatitis."—E. B., aged fifty-five years; admitted to the Presbyterian Hospital December 6, 1902. Patient has always been well. No history of venereal difficulty. No alcoholic habit. Three days before admission to the hospital, after exposure to cold, patient suffered from a chill, with pain in the lower right side of the chest, both in front and behind, the right hypochondrium being sensitive to pressure. There was fever, cough, which was dry, prostration, and the patient was confined to bed. The pain persisted and was cutting in character; it was intensified by deep inspiration. The bowels were constipated and the urine was high-colored.

Examination on Admission.—The conjunctivæ are icteric. The entire abdomen is rigid, the rigidity being most marked in the right upper quadrant over the region of the gall-bladder. There is a very distinct resistance of the upper half of the right costal arch. The temperature varied between 101° and 104° F., the pulse from 88 to 104. The leucocytosis in several examinations varied between 16,000 and 20,000.

Operation (Chloroform).—A vertical incision was made parallel to the outer margin of the right rectus. The lower part of the peritoneal cavity was free from adhesions, but there was a distinct increased intra-abdominal tension characterized by the tendency of the intestines to prolapse through the abdominal incision. The gall-bladder and ducts were normal. Exploration of the liver with a hypodermic needle gave a negative result. The entire upper surface of the right lobe of the liver was joined to the diaphragmatic and parietal peritoneum by numerous adhesions of varying density which were separated from their point of attachment on the liver only with considerable difficulty. In other respects, the liver appeared normal. The adhesions were broken up, and the abdominal wound closed in layers, a cigarette drain being left in the lower angle.

Postoperative.—On the morning after the operation the patient declared that he was free from pain and that he felt very much better. The improvement steadily continued, and at the end of a week both the pulse and temperature had returned to normal. The would healed *per primam,* and at the end of four weeks the patient returned to work feeling perfectly well. December, 1903. Patient has enjoyed excellent uninterrupted health since the operation.

Case XI. Sarcoma of the liver.—K. H., aged forty-nine years; admitted to the Presbyterian Hospital March 2, 1903. Previous history negative. About eighteen months ago patient suffered from occasional sharp pains in the right iliac and lumbar regions. These occurred in attacks about once a month and were accompanied with vomiting. A physician, called in attendance at that time, diagnosed "abdominal tumor." These symptoms continued until five weeks ago, when the pain became more severe and was brought on by the slightest exertion. For the greater part of that time the patient has remained in bed. The bowels have been habitually constipated. There has been no jaundice. There has been considerable loss of flesh and strength.

Examination on Admission.—There is asymmetrical bulging of the abdominal wall, the right side being protruded by some underlying growth which extends a distance of three inches to the left of the median line. Above, it disappears beneath the costal arch, and below, in the median line, it extends to within two inches of the symphysis. There is asymmetrical respiratory movement of the costal arches, the right remaining almost motionless during expiration. On palpation, the bulging is found to be due to the presence of an abdominal growth moderately elastic, yet of firm consistency, with a smooth surface. Above, it is lost beneath the right costal arch, which cannot be depressed toward the vertebral column, and below, by rectal examination, the mass can be felt to occupy the upper part of the pelvis. Percussion over the tumor yields a flat note, continuous above with the liver flatness. The mass can be removed slightly from side to side without much discomfort to the patient.

Operation (Gas and Ether).—Incision parallel to the outer border of the right rectus, extending upward above the level of the umbilicus. On opening the peritoneal cavity, the mass was found to be adherent to, and to infiltrate extensively, the anterior abdominal wall. The abdominal wound was closed after a portion of the tumor had been removed for subsequent microscopical examination.

Postoperative.—The patient recovered from the effects of the operation, but her general condition gradually became weaker ,and death occurred in about two weeks. Microscopical examination of the tumor, which was evidently primary in the liver, showed it to be a spindle-cell sarcoma.

Case XII.—L.L., male, aged thirty-five years; admitted to the Presbyterian Hospital April 14, 1902. Moderate alcoholic habit. There is no history of colitis. About nine months ago patient suffered from an attack of catarrhal appendicitis, from which he recovered without operation. With this exception he has always been well and able to work. Ten days ago he was suddenly seized with severe pain in the epigastrium, equally pronounced on both sides. It was accompanied by chill, followed by fever and sweating. There was no vomiting. These symptoms have continued except for short intervals, the pain being so severe as to interfere with sleep.

During the past week the pain has become localized in the right hypochondrium and epigastric regions, and tenderness has developed. The bowels have been constipated, no movement have taken place for the last three days. The stools have been of normal color. There has been no jaundice. During this time the prostration has been sufficient to confine the patient to bed.

Examination on Admission.—There is diminished respiratory movement of the upper part of the abdomen and of the costal arch. On palpation, in the middle line, extending from the ensiform appendix to within one inch of the umbilicus, is a mass of which the surface is smooth, the consistency elastic. It is tender under pressure, and extends farther to the right than to the left of the median line. The pain is increased by deep respiration and also by efforts to turn the body from right to left. The mass moves up and down with the respiratory movement of the liver. There is rigidity of the upper portions of both costal arches, more marked, however, on the right than the left side. There is some rigidity of the adjacent portions of the recti muscles. The temperature is 102° F., varying between 101° and 103° F. The pulse remains under 100. There is 15,000 leucocytosis.

Operation (Gas and Ether).—Incision in the median line above the umbilicus. The wall of the abscess cavity was found adherent to the parietal peritoneum, and the cavity was opened, evacuating about one pint of pus, without entering the general peritoneal cavity. The size of the abscess cavity was about that of an orange, and the pus was thick and of a red color. Partial suture, with a rubber drain enveloped in gauze.

Postoperative.—There was immediate relief from the pain, with prompt return of both pulse and temperature to normal. The abscess cavity gradually closed by granulation without the leakage of bile. For weeks after the operation, a sinus, about one and one-half inches deep, remained, subsequently closing. December 1, 1902. Patient had enjoyed excellent health since leaving the hospital. A slight rupture has developed in the lower part of the cicatrix.

Case XIII.—R. D., male, aged twelve years; admitted to the Presbyterian Hospital November 2, 1902. With the exception of chronic ear difficulty following one of the exanthemata, patient has always enjoyed excellent health. On October 17 last, patient was operated on at the Manhattan Eye and Ear Hospital of this city for mastoiditis with thrombosis of the lateral sinus. The mastoid cells were thoroughly opened and the internal jugular vein ligated about the center of the neck. The patient made an excellent recovery from the effects of the operation, both pulse and temperature becoming normal at the end of the tenth day, and both the wounds presenting a healthy granulating appearance. Two days ago, without known cause, patient developed very sharp pain in the right hypochondrium. This pain was manifested in attacks of several minutes' duration, at intervals of from half an hour to one hour, and was accompanied by a rise in temperature to 102°, and of the pulse to 130. There was no chill. During the next twenty-four hours the pulse rose to 180, the temperature to 104°, and the patient was transferred to the Presbyterian Hospital for possible operation.

Examination on Admission.—On inspection, there is a marked bulging of the right hypochondrium, extending as low as the level of the umbilicus. The corresponding portion of the costal arch is displaced forward and shows diminished respiratory movement. On palpation, the mass is smooth, elastic, and very tender, moving up and down with respiration. There is very pronounced rigidity of the overlying costal arch and of the adjacent muscle. There is slight rigidity of the left costal arch. Patient lies on the right side with the thighs flexed, any change from this position intensifying the pain. There is 23,000 leucocytosis.

Operation (Chloroform).—A vertical incision was made along the outer border of the right rectus, extending from the costal arch downward. On opening the peritoneal cavity, a small amount of serous fluid escaped, and the enlarged right lobe of the liver bulged prominently into the wound. A needle inserted into the most prominent part of the right lobe withdrew turbid opaque fluid of a gray color and entirely free from odor, at a depth of about two inches. The track of the needle was enlarged with the cautery and several ounces of this fluid evacuated. The cavity was drained with both gauze and tube.

There was considerable restlessness for twenty-four hours. Both pulse and temperature fell slowly for six days to 101° and 100° F. respectively. There was then, without known cause, a shoot of temperature to 104° F., and of the pulse to 120, without wound-disturbance discoverable. Both gradually subsided, reaching normal at about the end of a month. There was no vomiting at any time, the patient taking considerable quantities of fluid nourishment.

The discharge from the wound was yellow and abundant for the first ten days, gradually diminishing as the cavity closed. At the end of a month a superficial sinus only remained. At this time no enlargement of the right lobe could be detected by bimanual examination. Seven weeks after the operation patient left the hospital entirely healed, and remained in excellent health until the following April 21, when he was readmitted suffering from bronchitis and a pleurisy over the lower part of the right lung. Both of these conditions disappeared in the course of ten days, and since that time there has been no further trouble.

Through a misunderstanding, the fluid removed was not subjected to a rigid examination. Cursory examination showed it to contain a considerable number of leucocytes, and to be relatively free from any of the bile constituents.

Case XIV.—A. M., male, aged thirty-one years; admitted to the Gouverneur Hospital May 29, 1902. Previous history negative. Several days before admission patient developed the symp-

toms of fever, which did not subside, and he was brought to the hospital. On admission he was found to be probably suffering from typhoid fever, the diagnosis being subsequently rendered certain by the presence of the "Widal" reaction. For the first three weeks the course of the fever presented nothing materially different from the typical case. During the fourth week there was an increase in the temperature and in the rapidity of the pulse; at the same time the patient complained of pain in the right hypochondrium over the region of the liver. Examination showed rigidity of the upper part of the costal arch with tenderness on pressure. No enlargement of the liver could be detected. There was a leucocytosis of 15,000. Exploration was advised, but refused until July 2. During this time the pain and tenderness increased and the curve of the temperature was that ordinarily seen in collections of pus. The rigidity of the arch had also extended to its lower portion.

Operation (Gas and Ether).—Through a vertical incision parallel to the outer border of the right rectus above the umbilicus the peritoneal cavity was opened and the upper surface of the liver exposed. At a depth of two inches in the right lobe an abscess cavity was detected and pus withdrawn with a hypodermic needle. The pus was evacuated, the liver tissue being divided with a cautery, along the needle as a guide. Drainage with tube and gauze.

Postoperative.—The patient reacted well from the operation and was considerably relieved, there being marked improvement in both the local and constitutional symptoms. The upper portion of the arch resumed its normal resiliency, but the lower portion still remained rigid. Before the expiration of a week the temperature and pulse became higher, and pain and tenderness developed over the region of the liver behind, the resistance of that portion of the arch becoming more marked. There was also an increase in the pre-existing leucocytosis.

Operation July 16 (Gas and Ether).—An oblique incision was made parallel to the twelfth rib posteriorily, the rib excised subperiosteally, and the lowest angle of the pleural cavity opened. There were no adhesions. The opposite diaphragmatic pleura bulged into the wound and, after the withdrawal of pus with a needle, the diagram was incised, opening a large subdiaphragmatic abscess extending into the posterior portion of the right lobe of the liver. This was drained with gauze and diaphragmatic surfaces. The patient reacted well from the operation and drainage was very satisfactory. There was marked subsidence of the local pain and tenderness. The temperature, though somewhat lower, still ran a pyemic course, and the patient gradually became weaker, dying from exhaustion five weeks later.

Case XV.—E. F., male, aged forty-eight years; admitted to the Presbyterian Hospital February 25, 1901. Patient is an Italian, and a satisfactory past history is difficult to obtain. Five weeks ago he was treated in one of the city hospitals with the history of pain in the back and the right hypochondrium for an indefinite length of time. There were no constitutional symptoms of fever. On exploratory operation, the liver was found to extend two inches below the level of the costal margin. Aspiration of the right lobe withdrew no fluid. The abdominal wound healed *per primam,* but the patient developed an irregular temperature and some jaundice, with progressive loss of flesh and strength. The pain in the right hypochondrium still persisted.

Examination on Admission.—The patient is poorly nourished and cachetic. There is slight icterus. There is a well-marked projection of the right hypochondrium, the respiratory movement of the costa larch being diminished. There is dilatation of the surface veins. On palpation there is a smooth mass, deeply seated, projecting inferiorly below the level of the costal margin, a distance of two inches, of which the lower border is indistinct. There is well-marked rigidity of the corresponding portion of the costal arch and of the adjacent rectus muscle, with some tenderness on pressure over the center of the tumefaction. Patient's temperature ranged from 101° to 102° F., the pulse around 100. There was moderate leucocytosis.

Operation (Gas and Ether).—A vertical incision was made along the upper outer border of the right rectus in the line of the cicatrix. On opening the peritoneal cavity there were no adhesions. The right lobe of liver was enlarged and projected several inches below the costal margin. A needle inserted into its prominent portion withdrew pus at the depth of about one and one-half inches. The pus was thick and of a creamy-yellow color. The needle was left *in situ,* iodoform gauze being packed around its point of emergence from the liver, thus shutting off the peritoneal cavity, and at the end of four days the abscess cavity was thoroughly opened along the line of the needle with the Paquelin cautery. The cavity was about the size of a cocoanut, and contained over a quart of pus.

Postoperative.—There was gradual subsidence of both pulse and temperature, reaching normal on the sixteenth day. There was immediate cessation of the pain. For the first few days the discharge from the abscess cavity was very profuse, and contained a considerable amount of bile. It then gradually diminished, and at the end of two weeks was very slight. On the sixteenth day after the operation, pain developed in the left hypochondrium, and the biliary fistula manifested a marked increase in activity. There was a rise in both pulse and temperature. The leucocytosis was again increased to from between 12,000 and 16,000. On examination, there was rigidity of the left costal arch near the junction of the eighth and ninth costal cartilages and of the adjacent rectus muscle, with tenderness on pressure. After four days the patient finally consented to an exploratory incision.

Second Operation (Gas and Ether).—A verti-

cal incision was made along the outer upper border of the left rectus. The peritoneal cavity showed evidence of adhesion. The left lobe of the liver was normal in appearance. A needle inserted, however, withdrew a small amount of pus at a depth of two inches. The opening was immediately enlarged with the cautery and several small abscess cavities enlarged into one with the finger. Rubber tube and gauze drainage.

Postoperative.—The patient made an excellent recovery, both local and constitutional symptoms disappearing promptly. The discharge from the biliary fistula on the right side rapidly decreased, and on leaving the hospital the patient had gained weight and was in very much better condition than at the time of his admission. June, 1902. Patient has gained forty pounds during the past year and has enjoyed excellent health. No culture could be found in the pus.

Case XVI. Subdiaphragmatic Abscess Complicating Acute Appendicitis.—M. H., aged eight years; admitted to the Presbyterian Hospital June 20, 1901. Previous history negative. Five days ago patient was seized with sudden severe pain in the right lower quadrant of the abdomen. At the end of two days, during which time the pain recurred at intervals, patient developed vomiting, diarrhea, and prostration, with excessive abdominal tenderness. The vomiting and diarrhea ceased at the end of twenty-four hours, but the weakness and prostration persisted and became more pronounced.

Examination on Admission.—The entire abdomen is swollen, especially on the right side. There is no expiratory recoil of the right costal arch. Moderate recoil of the left arch. The right half of the abdomen is excessively tender and rigid. The right costal arch is protruded slightly forward and cannot be depressed even for a short distance toward the vertebral column. There is some rigidity of the left abdominal wall, especially in the lower half, but it is less marked than on the right side. The temperature is 104° F., the pulse 140 and weak, the respiration 46. Leucocytosis taken twelve hours after operation amounted to 17,000.

Operation (Gas and Ether).—Incision along the outer border of the right rectus muscle, extending from the region of the appendix to the costal arch above. The opening of the peritoneal cavity was followed by the evacuation of a large amount of pus, which distended a cavity reaching from the brim of the pelvis below to the lower surface of the diaphragm above, extending both in front of and behind the liver. That portion of the pus situated in front of the liver escaped only after the costal arch was elevated by the surgeon's hand. The appendix was gangrenous and was removed by ligation and cauterization of the stump. The abscess cavity was carefully cleansed with peroxide of hydrogen and was drained both above and below with tubes and strips of gauze, a counter-opening being made posteriorly along the lateral margin of the colon, and a gauze tampon being introduced between the upper surface of the liver and the anterior abdominal wall. The middle part of the wound was held together with one suture.

Postoperative.—On the day following the operation temperature rose to 106° F., the pulse varied between 150 and 160, and there was considerable restlessness and delirium. There was no vomiting nor tendency to an increase in the distention, and the patient retained a considerable amount of fluid nourishment. There was moderate peristalsis over the left side of the abdomen. On the second day flatus escaped from the rectum, the bowels moved, and there was progressive diminution of both pulse and temperature, reaching 120 and 103° F. respectively on the third day. From this time on, there was gradual improvement, continuing for two weeks and a half, the temperature ranging between 101° and 102° F., the pulse around 120, and the wound draining very freely both in front and behind. At the end of this time the constitutional symptoms of sepsis increased in severity and there seemed to be slight retention of pus in the upper portion of the wound. Three days afterward expectoration of pus occurred, followed by symptoms of collapse and the death of the patient. No autopsy was allowed, but the extension of the suppurative process along the lymphatics in the diaphragm had evidently not been successfully checked by the operation and had caused the fatal issue.

Case XVII. Acute Pancreatitis.—E. P., male, aged twenty-eight years; admitted to the Presbyterian Hospital June 13, 1901. Previous history negative. Three days before admission the patient experienced some abdominal pain, with one attack of vomiting and general malaise. The bowels were constipated and failed to move since. There was no chill. The prostration steadily increased, and the abdomen has become more tender and moderately distended. He has taken no nourishment. His chief complaints are pain and prostration.

Examination on Admission.—Patient is a well-nourished and muscular man. The entire abdomen is markedly distended. The abdominal pain is general and not referred to any one point. On palpation, there is general abdominal rigidity, most marked in the right upper quadrant. There is increased resistance in the upper part of the right costal arch. There is slight dulness in both flanks, especially the right. On auscultation, peristaltic sounds are heard over the entire abdomen. The urine has a specific gravity of 10.44, is of acid reaction, contains twelve per cent. (by volume) of albumin, and on microscopical examination numerous hyaline and granular casts are found. On admission, temperature was 103° F., the pulse 124 and very weak, and the respiration 28. There was a leucocytosis of 27,000.

Operation (Gas and Ether).—An incision four inches long was made along the outer border of the right rectus above the umbilicus. The peritoneal cavity contained considerable quantities of dark-brown fluid not encapsultated and most

abundant in the right upper quadrant. As it was sponged away, it seemed to be renewed by similar fluid emerging from the foramen of Winslow. The small intestine was moderately distended. The gall-bladder, the gall-ducts, and the appendix were normal. The head of the pancreas was swollen and of peculiar "boggy" consistency. After the careful cleansing of the upper right peritoneal cavity a Mikulicz drain was inserted down to the region of the foramen of Winslow, and the lower part of the wound closed by interrupted suture. Although the operation was quickly performed, the patient's pulse became so feeble as to require an infusion.

Postoperative.—On the day after the operation the pulse rose from 132 to 150 and could scarcely be felt at the wrist. The temperature varied between 103° and 104° F. The patient was restless and perspired profusely. There was no vomiting, and the patient retained considerable quantities of fluid nourishment. Owing to the weak condition of the pulse, hypodermoclysis was given. On the second day after operation the pusle varied between 130 and 140 and was slightly stronger. The temperature varied between 102° and 103° F. The extremities, which had been cold, became warmer. Several hours after the administration of a laxative, there were several dejections consisting of solid and semi-solid brownish material. The patient declares that he feels perfectly comfortable. From this time on there was steady and gradual improvement, the temperature reaching normal on the sixteenth day. Four weeks after the operation the patient left the hospital with a small sinus. The subsequent history of the patient is unknown, repeated endeavors to communicate with him have failed.

Case XVIII. Large Pancreatic Cyst.—A. B. M., male, aged thirty-nine years; admitted to the Presbyterian Hospital October 6, 1902. Patient's sister had an ovarian cyst. Patient was a hard drinker of whisky until several years ago, since which time he has touched no liquor of any kind. Has always used tobacco in moderation.

Seven years ago patient was seized with an attack of sharp pain, knife-like in character, referred to the left hypochondrium and intensified by inspiration. It was accompanied by vomiting and prostration, the former ceasing after several days, the latter being so severe as to confine the patient to bed for five weeks, during which time the attending physician noticed a swelling in the left side, which was so small as not to be appreciated by the patient. These attacks were repeated, recurring at first every month, subsequently at increasing intervals, until two years ago, at which time they ceased entirely. No attack lasted for more than forty-eight hours, nor did any attack confine the patient to bed.

The tumor has steadily increased in size, especially at the time of an attack, and for the past six years has been noticeable to the patient. There has been progressive loss of flesh and strength, the patient weighing thirty pounds less than he weighed seven years ago, and the weakness having become more pronounced during the past two years, and there has been some shortness of breath. At present the swelling has reached so large a size as to be inconvenient, and this, together with the general weakness and shortness of breath, constitute the chief complaints.

Examination on Admission.—The abdominal cavity is the site of an asymmetrical swelling involving the entire left side and extending for a distance of three inches, in its most prominent portion, to the right of the median line. The greatest convexity of the overlying abdominal wall is seen in the left upper quadrant, and the corresponding portion of the costal arch is pushed prominently forward and has no expiratory recoil. There is also extensive bulging of the left flank and ileo-costal space. On palpation, the tumor is smooth, of elastic consistency, and by bimanual examination a fluid wave may readily be detected passing from its upper right to its lower posterior portion in the ileocostal space. There is no fremitus. The portion of the tumor overlying the abdominal aorta left costal arch, and any effort to depress it toward the vertebral column encounters distinct elastic resistance. There is slight descent of the mass during inspiration. On percussion, the entire tumor is flat, being continuous above with the area of cardiac dulness and obscuring the normal area of splenic dulness. The intestinal resonance is situated chiefly in the lower right quadrant of the abdomen. By inflation, the stomach and descending colon are found to lie anterior to the cyst. Repeated examination of the stools give no evidence of the presence of undigested fat, and there is no glycosuria or other abnormal condition of the urine. The general condition of the patient is fair, the heart action of good force and regular.

Operation. October 15 (Gas and Ether.—Vertical incision two and one-half inches from the median line, extending an equal distance above and below the level of the umbilicus, and situated over the most prominent part of the tumor. On opening the peritoneal cavity, the smooth, pearly cyst-wall presented, with the splenic flexure lying on its anterior surface. This was reflected with some difficulty a short distance toward the median in order to bring the contemplated opening through the cyst wall directly opposite the abdominal incision. The entire cyst was retroperitoneal and so firmly adherent to the stomach, the colon, the spleen, and the posterior abdominal wall, as to render any enucleation impossible. The cyst was therefore emptied of its contents, consisting of several gallons of yellow turbid fluid, with a trocar and canula, and its interior explored through an incision in its anterior wall. In this manner the left kidney could be distinctly palpated behind it, and the pancreas, also posterior, could be felt a little higher up and near the median line. A counter-opening was made to the outer side of the kidney in the left ileocostal space, a portion of the cyst-wall being here excised without difficulty. The edge of the anterior opening in the cyst-wall was sutured to the cor-

responding edge of the divided parietal peritoneum, and after the insertion of drainage-tubes both in front and behind, into the cyst cavity, the upper and lower extremities of the abdominal incision were closed by suture.

Postoperative.—There was some vomiting and hiccough for several days, and the bowels moved with rather more difficulty than usually, responding to catharsis on the third day, followed by subsidence of the above symptoms. At no time was the pulse higher than 80, and there was but slight temperature elevation. The discharge from the anterior of the cyst was very slight. During the next ten days the bowels moved regularly, and patient was very comfortable, complaining only of occasional abdominal cramp-like pains. October 27. Patient vomited several times this afternoon. Bowels moved freely with enema. There was no rise in the pulse or temperature. October 28. Patient vomited again to-day. Some cramp-like abdominal pains developed. Bowels again moved after an enema. There was no abdominal tenderness. Pulse and temperature still continued normal. Some local distention developed in the right iliac fossa, evidently due to an inflated cecum. October 29. Distention increased, and the pulse rose to 100, the temperature to 101° F. An exploratory incision was deemed advisable. Under ether, an incision was made over the outer border of the right rectus, below the umbilicus, and the peritoneal cavity was found to contain a considerable amount of fluid fecal material. The perforation could not be found nor could its cause be ascertained. Drainage. Patient rapidly became worse and died the following morning.

Autopsy.—The site of the perforation could not satisfactorily be located. The cyst was found to spring from the tail of the pancreas.

Case XIX.—M. K., aged twenty-four years; admitted to the Presbyterian Hospital August 27, 1900. Eleven years ago patient was thrown from a wagon, but was not incapicated. Between two and three years later, kyphosis developed in the dorsolumbar region, requiring the application of an orthopedic corset.

Nine months ago, without known cause, painful and frequent urination suddenly developed. There were burning sensations over the bladder, intensified by micturition. Patient passed urine every two or three hours during the day and several times during the night. The urine was cloudy and "thick." These vesical symptoms have continued up to the present time, notwithstanding frequent irrigations of the bladder and the advantages of a change in climate. There have been progressive loss of flesh and strength and increasing anemia.

Examination on Admission.—There is a tender rounded mass in the left lumbar region, extending from the level of the crest of the ileum below to beneath the costal arch above and to within 1½ inch of the median line internally. The mass is lobulated, of elastic consistency, and slightly painful on pressure. The lower segment of the costal arch is distinctly rigid, and pressure on it elicits pain. By percussion the descending colon is found to lie anterior to the tumor. The mass descends slightly on respiration. Catheterization of the ureters by Dr. F. Tilden Brown elicited the fact that the urine from the right kidney was normal, while that from the left was scanty and contained large amounts of pus and cheesy material. Examination failed to detect the presence of tubercle bacilli in the urine of either kidney. The trigone was the site of numerous patches of ulceration, which were most abundant around the mouth of the left ureter. The patient's temperature varied between 100° and 104° F., the pulse between 100 and 120. There are physical signs of a healed tuberculous process in the upper part of the left lung.

Operation (Chloroform, followed by Ether).—The left kidney was exposed by a vertical incision along the edge of the erector spinæ, from the lower extremity of which a horizontal incision extended forward toward the umbilicus. The perirenal fat was scanty. The kidney was easily enucleated. It was double the normal size and irregularly lobulated, presenting the appearance of a multilocular pyonephrosis. The pedicle was ligated with heavy catgut. The ureter was traced downward to a point below its crossing of the external iliac vessels and was removed. It presented a beady appearance, and the part which crossed the brim of the pelvis was materially thickened and intimately adherent to the posterior parietal peritoneum and the iliac vessels. Irrigation of the wound followed by closure with chromic gut in layers, a cigarette drain having previously been inserted in the lower angle.

Postoperative.—The patient reacted well from the operation. During the first forty-eight hours there was considerable nausea, but the patient retained a moderate amount of fluids and passed twenty ounces (plus) of urine daily. Movement of bowels took place on the third day. The increased frequency of urination persisted, the urine, however, containing a small number of leucocytes only. The temperature varied between 100° and 103° F., gradually decreasing and reaching normal at the end of the second week. The wound healed down to the drain. At the end of five weeks, patient's general condition was more satisfactory than just prior to the operation. November 20. Since last note the patient has been gaining rapidly in strength. The sinus had closed and reopened. To-day, patient developed what proved to be a pleurisy with effusion on the left side. After three weeks this subsided, leaving the patient very weak. Slow convalescence. December 1, 1903. For the past six months the general condition of the patient has steadily improved. She has completely recovered, with the exception of the persistence of the increasing frequency of micturition at night, which, however, is not painful.

Case XX.—W. S., aged nineteen years; admitted to the Presbyterian Hospital May 18, 1903. General health has always been excellent. About

two months ago, patient was seized with severe sharp lumbar pain. Shortly afterward, the urine became cloudy. The pain at first was not sufficiently severe to interfere with the pursuit of the patient's studies. At the end of a month, patient was compelled to give up work, and consulted a physician. An exploratory lumbar incision was made in the lumbar region over the right kidney by a surgeon in a neighboring city and was completely closed by suture, healing by primary union within three weeks. The symptoms continued, and to the pain were added chilly sensations, and an irregular febrile movement with progressive loss of flesh and strength. Recently a tumor in the right flank has been noticed.

Examination on Admission.—There is a distinct bulging of the right flank, which is found to be occupied by a tumor reaching down into the right iliac fossa, extending upward beneath the right costal arch and as far forward as the edge of the rectus. It is smooth, highly elastic, and by bimanual examination fluctuation can be elicited. It is moderately tender. By percussion, the ascending colon lies anteriorly. There is well-defined rigidity of the lower segment of the right costal arch, and pressure on it causes pain. The temperature varies between 100° and 103° F.; the pulse varies between 90 and 110. There is leucocytosis. The urine is high-colored and contains only a small number of leucocytes, although previously it had contained considerable quantities of pus.

Operation (Gas and Ether).—The cicatrix of the previous operation was excised by an elliptical incision, which was deepened until the perirenal fat came into view. The enlarged kidney, surrounded by a very small quantity of fatty tissue, was readily enucleated, and its pedicle ligated with heavy catgut. The organ was more than double the normal size and was the site of a number of abscesses, one, consisting, of the dilated pelvis, of very large size. The temporary plugging of the ureter, which was in other respects normal with cheesy tubercular material, accounted for the fact that the bladder urine contained a small number of leucocytes only. The wound, after irrigation with salt solution, and the insertion of a cigarette in its lower angle, was closed by chromic-gut suture.

Postoperative.—The patient reacted well from the operation. There was no nausea. There was no diminution in the daily amount of urine. The temperature rapidly decreased, becoming normal at the end of the first week. The wound healed kindly, and at the time of discharge had almost closed. The patient's general condition continued to improve and he left the hospital much stronger than he was at the time of admission. December 1. The sinus has closed and reopened once or twice. His general condition has steadily improved.

Case XXI. Peri-nephritic Abscess.—M. P., aged fifty-nine years; admitted to the hospital October 23, 1902. Previous history negative. Three weeks ago, without known cause, slight tenderness appeared in the left lumbar region, with increasing prostration and loss of appetite. There was an irregular febrile movement. The bowels were regular, and urination was normal and regular. Four days ago the patient noticed a lump in the left flank. The prostration has confined the patient to bed for the past week. The chief complaints are the pain and the prostration.

Examination on Admission.—The left ileo-costal space is the site of a bulging mass, most prominent posteriorly. In front it extends to the margin of the rectus muscle. Behind, the overlying skin is slightly reddened and the tenderness most marked. There is rigidity of the lower segment of the costal arch. The tumor is everywhere dull, except where the descending colon passes anteriorly. The temperature is 101° F., the pulse 100, and there is 30,000 leucocytosis.

Operation (Gas and Ether).—An incision beginning near the border of the erector spinæ muscle and passing obliquely forward and downward in the ileo-costal space, was made over the most prominent part of the tumor. With the division of the transversalis fascia, a large abscess-cavity was opened, the pus being of dark brown color and very foul. By bimanual examination the kidney could be felt anterior to the wall of the abscess-cavity. The cavity was thoroughly irrigated with saline solution, and after the insertion of a good-sized rubber drain in the most dependent angle of the wound, its extremities were closed by interrupted chromic-gut suture.

Postoperative.—There was immediate relief of the pain and tenderness and a gradual subsidence of the fever. The abscess-cavity rapidly contracted, and at the time of discharge, three weeks later, only a sinus two inches in depth remained. This subsequently closed. June, 1903. Patient has enjoyed health during the past six months.

Case XXII.—M. C., aged twenty-eight years; admitted to the Presbyterian Hospital October 2, 1903. Patient has always been a moderate tea-drinker. Previous history negative until five months ago, since which time the appetite has been poor and the patient has been disinclined to eat solid food. There was no pain or vomiting, however, until one month ago. At that time a sharp shooting pain developed in the epigastrium, coming on suddenly in attacks of several minutes' duration without reference to the ingestion of food, and radiating in every direction. These symptoms were not sufficient to confine the patient to bed, nor was there any vomiting until the night before admission. At that time, the pain suddenly became very intense, and vomiting developed and was continuous. There was syncope, and the patient was obliged to discontinue work. The vomitus consisted of partially digested food, and afterward of mucus. At no time was there hematemesis of blood in the stool.

Examination on Admission.—The entire abdomen is distended and very rigid, the rigidity being most marked in the upper left quadrant. There is increased resistance of the left costal arch, the rigidity being most pronounced in its

upper portion near the junction of the eighth and ninth costal cartilages. The abdomen is everywhere tender, especially at a point about three inches above the umbilicus and just to the left of the median line. The abdomen is everywhere tympantic, and there is loss of liver dulness. The patient lies in the dorsal position with the thighs flexed, and any lateral movement of the trunk or extension of the thighs is very painful. The pulse varies from 105 to 120, the temperature ranged around 101° F. The patient's general condition bordered on collapse.

Operation (Gas and Ether).—Median incision, extending upward from the umbilicus a distance of three inches. The opening of the peritoneal cavity permitted the escape of a large amount of gas, which was free from odor. A small amount of serous fluid of neutral reaction was sponged away from the anterior surface of the stomach, which presented in the wound free from adhesions. The depression of the anterior surface of the stomach from the parietal peritoneum in the direction of the pylorus was followed by the escape of an increased amount of fluid of neutral reaction. It was more turbid than that originally observed on opening the peritoneal cavity. The pylorus was, however, free from perforation. Through a small opening in the gastro-colic omentum, the posterior surface of the stomach and the lesser peritoneal cavity were then found to be normal. The stomach was now depressed toward the cardiac extremity, and the escaping fluid became markedly increased in quantity as well as in turbidity, and contained particles of partially digested food, disclosing shortly the presence of a perforation about three inches from the cardia and midway between the greater and lesser curvatures. The adjacent fluid was of distinctly acid reaction. The perforation was about the size of a lead-pencil, and the edges of the orifice were well defined and soft. No induration could be detected in the adjacent stomach-wall. A purse-string suture of chromic gut was taken in the healthy wall of the stomach and the orifice closed. Two Lembert sutures of silk were then inserted over the tightened purse-string suture, and the adjacent peritoneal cavity carefully cleaned. After the insertion of drains down to the pylorus and point of perforation, the remaining portion of the abdominal wound was closed.

Postoperative.—Some nausea and vomiting for twenty-four hours. The pain greatly diminished, and the patient felt very much more comfortable. The evacuation of the free gas in the peritoneal cavity was directly followed by the disappearance of the distention, and the lower half of the abdomen remained flaccid and free from rigidity throughout. The pulse ranged around 120, but was of very much better quality than prior to operation. The temperature remained below 101° F. There was no discharge of stomach contents from the wound, and the patient received increasing quantities of fluid nourishment without pain or discomfort. During the second twenty-four hours the pulse had decreased to 80, and thereafter the progress was very satisfactory. October 12, 1903. Patient's temperature to-day suddenly rose to 103.5° F., the pulse to 120, and in the course of the next forty-eight hours, the physical signs of consolidation of the lower left lobe developed with a serous effusion in the left pleural cavity. This complication ran its regular course, terminating in resolution on the twelfth day. Shortly after, the temperature became normal, and further convalescence was uneventful. At time of discharge the sinus persists, but is superficial, and the patient's general condition is satisfactory.

Case XXIII.—P. G., male, soldier; admitted to Gouverneur Hospital June 15, 1903. Previous history negative. Patient denies ever having had syphilis. On the day of admission to the hospital, patient, who had hitherto always enjoyed excellent health, was seized with paroxysmal pain in the left abdomen. The pain, most intense on the left side, radiated down the left thigh as far as the knee and also to the opposite side of the abdomen. The patient was obliged to cease work immediately and came to the hospital to obtain relief from the pain, a relief afforded only by the hypodermic use of morphine.

Examination on Admission.—There is a large pulsating tumor occupying the left side of the abdomen. The pulsation is synchronous with the heart-beat and of an expansile character. On palpation the tumor has a smooth surface, and by bimanual examination can be distinctly felt to completely fill the entire lumbar region, extending from the crest of the ileum below to the costal arch above. There is rigidity of the left costal arch, most marked in its lower posterior portion. On ausculation, a distinct systolic bruit may be heard over the tumor. There is no disturbance of the circulation in the lower extremities, nor any asymmetry of the posterior tibial pulse. June 21. There has been no change in the size of the tumor since admission. The pain is so intense that willing consent is given for an exploratory operation. This was undertaken in the hope that an aneurism of the renal or other branch of the aorta might be found which then could be removed by ligation and excision.

Operation (Gas and Ether).—The abdomen was opened by an incision along the outer border of the left rectus, extending for an equal distance above and below the umbilicus. The aneurismal sac was in close contact with the parietal peritoneum and had a thin wall. It extended from the spleen above to the iliac fossa below, and involved the aorta from a point just below the diaphragm to within two inches of the bifurcation. The abdominal incision was closed with some difficulty owing to the pressure of the sac against the abdominal wall. For one week the patient experienced great relief from the pain. Then the pain recurred with its former intensity. Three weeks after the operation, rupture of the sac took place through the upper part of the healed incision, and death resulted from hemorrhage.

Remarks.—The cases of surgery of the liver

here reported, constitute a very large group of those cases in which the symptom of costal resistance may be elicited. In those of acute character, such as abscess and inflammation of the gall-bladder, the symptom has been invariably obtained. It has also been obtained in many other cases of cholecystitis, the histories of which are purposely omitted because no confirmation of the pathological condition could be obtained, resolution either taking place or no operation being performed. In many cases of chronic inflammation, especially those associated with cholelithiasis in which the diagnosis was confirmed by an operation done in the interval between attacks, no costal resistance could be obtained, although the wall of the gall-bladder was found in a thickened condition and otherwise showed chronic inflammatory changes.

In neoplasm the symptom is of value only when the liver is materially increased in size as in Case VII; on the other hand, in cases of carcinomatous metastasis no definite change in the degree of costal resistance can usually be elicited, although the mass may not infrequently be palpated below the border of the arch.

Such malignant growths are, however, rarely if ever operable, whereas in abscess and acute cholecystitis, operation is not infrequently imperative. It is precisely in this latter group of cases, in which the presence of increased costal resistance is most constant. It is here often of the greatest value in making a differential diagnosis between acute liver and gall-bladder affections, on the one hand, and acute appendicitis, on the other, especially when the inflammatory process is so intense as to provoke symmetrical contraction of the entire rectus muscle. Under these circumstances the presence of costal resistance almost always excludes appendicitis. It is also desirable to call attention to the fact that, in subacute cholecystitis, manifested by local pain and tenderness with complete absence of all constitutional symptoms, a considerable degree of costal resistance is present.

Any detailed reference to the clinical features of these cases is foreign to this paper. At the same time, Case XV, in which an abscess developed in the left lobe of the liver some three or four weeks after the evacuation of a large abscess in the right lobe; Case XIV, in which typhoid fever was complicated by the formation of multiple abscesses in the right lobe; Case IX, in which acute cholecystitis existed without the presence of calculus, and Case VIII, in cholelithiasis in the quiescent stage in which pressure on the overlying costal arch elicited marked tenderness, are all worthy of special mention. In addition, the extreme variability in the clinical history of the early stages of cholelithiasis not only with reference to the local symptoms but also to the constitutional symptoms as well, should be emphasized.

Only one opportunity has been afforded to observe the behavior of the costal arch in acute pancreatitis. In this case, the presence of increased costal resistance was very pronounced, and indicated more than any other symptom the most advantageous incision for the diagnosis and relief of this most serious lesion. The case to which reference is made is also noteworthy in that prior to the operation as well as for twenty-four hours afterward, the general condition of the patient was most unfavorable to recovery, the radial pulse being nearly imperceptible, and requiring several clyses and infusions.

In cases of pancreatic cyst, the symptom of increased costal resistance occurs only when the cyst is so situated or has reached such dimensions as to lie beneath a segment of the costal arch. In the case here reported, the extraordinary size of the cyst accounted for the unusual prominence of this symptom.

The observation of this symptom in perforation of the stomach is unfortunately limited to one case, although this is one of considerable value in that, notwithstanding general rigidity of the entire abdominal wall, the resistance of the upper portion of the left costal arch was so much greater than the corresponding segment of the right side, that no hesitation was felt in making the incision above the level of the umbilicus. Shortly after another opportunity to test this symptom occurred in the case of a perforating ulcer in the anterior wall of the second part of the duodenum. Here again the entire abdominal wall was rigid, even when the patient was resting under the influence of morphine; the upper portion of the right costal arch, however, presented increased rigidity, and accurately determined the location of the incision.

Those pathological conditions of the kidney in which this symptom can be elicited are those in which the organ is increased in size or in which there is perinephric abscess. The writer has not yet had an opportunity to test the value of this symptom in acute pyelonephritis, a condition in which the size of the kidney, although greatly inflamed and the site of numerous abscesses, may yet be but slightly increased. One would naturally expect, however, to find this symptom in cases of this description.

In all cases of enlargement of the kidney, whether of an inflammatory or neoplastic character, the increased resistance is invariably most pronounced in the lower segment of the arch, and may be elicited with the patient in either the dorsal position or reclining on his side.

In several cases of calculi in the pelvis of the kidney which were removed by the writer during the past eighteen months, no change in the resistance of the lower costal arch has been noted. On the other hand, in two cases of intermittent hydronephrosis associated with movable kidney, the increased costal resistance was very pronounced. Also in one case of malignant growth of the adrenal, which was of large size, and partially cystic, the presence of this symptom was noted, although the character of the resistance was considerably less elastic than usual.

A careful analysis of the cases here reported

establishes the following conclusions: (1) That the symptom of costal resistance may always be elicited in the acute and subacute inflammatory processes of the contiguous underlying organs. In chronic inflammation of these same organs it is present irregularly, either generally, when the organ is increased in size, or during a transitory exacerbation of the chronic inflammatory process. In neoplasms or cysts, increased costal resistance may be obtained only when the tumor has reached a sufficient size to mechanically interfere with the movement of the arch. (2) That the degree of resistance is in direct ratio to the intensity of the inflammatory process. (3) That the increase of costal resistance is most marked in that segment of the costal arch which is closely situated to the original point of infection, or, in the case of neoplasm, to that part of the arch which lies over the most prominent part of the tumor. (4) That its value as a diagnostic symptom is greatest in pathological conditions invading the upper half of the abdominal cavity, especially of the liver, the stomach, the pancreas, the gall-bladder, the spleen, the duodenum, the kidneys, and in extensive aneurism of the abdominal aorta. The writer has had but little opportunity to observe this symptom in supradiaphragmatic processes. In cases of empyema, the abscess-cavity is generally encapsulated and does not usually occupy the lowest part of the thoracic cavity. Only when so situated is there resistance of the costal arch proper. In higher positions, any difference in the rigidity of the overlying rib or ribs is very difficult to detect and unsatisfactory. (5) That the presence of asymmetry in the elastic recoil is very much less frequently observed than asymmetrical increase in the costal resistance, the former being present only in cases of cysts, neoplasms, and inflammatory exudates in which the acute symptoms have subsided, while it is invariably absent in all the acute and subacute inflammatory. (6) That with the subsidence of the inflammatory process whether by radical or palliative procedure, the costal resistance again returns to its normal condition. (7) That the presence of this symptom is very valuable not only in facilitating accurate diagnosis, but also in serving as a useful guide to that incision through which the inflammatory focus may be most rapidly exposed and satisfactorily treated. (8) Finally, that proper and skillful technic in determining the presence or absence of this symptom may be easily acquired, and that, therefore, the application of the symptom may be utilized by the general practitioner and not confined to those engaged in the pursuit of any particular specialty.

Patient with Sutured Heart Leaves Hospital.—Thomas Emerson, the colored man for whom Dr. F. T. Stewart sutured a stabwound of the heart some two months ago, has been discharged from the Jefferson Hospital. For a time it was feared that an attack of pneumonia that began some days after the operation would prove fatal, but the patient fortunately recovered from both the wound and the complication.

A NEW METHOD FOR TRANSILLUMINATION OF THE STOMACH BY MEANS OF FLUORESCENT MEDIA: THE VALUE OF FLUORESCIN WITH A RESEARCH INTO ITS PROPERTIES.

BY ROBERT COLEMAN KEMP, M.D.,
OF NEW YORK;
CONSULTING PHYSICIAN, GASTRO-INTESTINAL DISEASES, MANHATTAN STATE HOSPITAL, WEST WARD'S ISLAND; PHYSICIAN DEPARTMENT OF GASTRO-INTESTINAL DISEASES, ST. BARTHOLOMEW'S CLINIC, ETC.

Drs. Cannon, Morton and others have already called the attention of the profession to the value of the internal administration of a fluorescent medium such as quinine, in order to enhance the action of the X-ray. The present article, however, has nothing in common with the latter. In the course of a series of experiments with transillumination of the stomach, the method of which Einhorn is the originator, I found that the employment of a liquid fluorescent medium, such as quinine bisulphate, gave better results than when plain water was used. In these cases, the patient drinks the fluorescent medium, is conducted into a dark room, and the electric light bulb is inserted into the stomach in the usual way.

For the past four months, demonstrations of the use of fluorescent media for stomach transillumination has been given at my Clinics at the Manhattan State Hospital, West, Ward's Island. During the first demonstrations, bisulphate of quinine solutions were employed, and the method was recently introduced by me, at the Manhattan State Hospital, East, Ward's Island, on the service of Dr. William H. Thomson, for whom I am visiting this institution at the present time. The technic was also described by me at a December meeting of the Post-Graduate Medical Society in this city, and an abstract was given to the *Post-Graduate Medical Journal.* An abstract of my subsequent experiments was given to the *New York and Philadelphia Medical Journal,* but the present article is the first *complete description* of the experiments so far published. My associates, Drs. John E. Traub and C. T. Graham-Rogers, were of invaluable assistance to me, and I am also much indebted to my friend, Prof. Achilles Rose, of the Post-Graduate Medical School. I am further indebted to Drs. Delacroix, R. Haviland and Meager of the hospital staff.

I shall first refer to the media that are suitable for stomach transillumination. I have at hand the names of at least half a dozen other fluorescent media, but they have never been administered internally and no literature is practically obtainable from the manufacturers. Further original investigation will therefore have to be carried out, as regards their properties and toxicity.

FLUORESCENT MEDIA.

1. *Quinine.*—Quinine bisulphate is more soluble and therefore preferable. Dissolve gr. x. quinine bisulphate in a glass of water and add to this ℥ v. acid phosphoric dilute. This seems to increase the fluorescence. Dilute sulphuric acid ℥ v. added to the quinine solution also increases

its efficiency, but the phosphoric acid gives better results. The patient drinks the glass of fluorescent water, follows it with a glass of plain water, and is then conducted into the dark room for examination. In daylight the color of the solution is a faint violet, the reaction acid and the fluorescence slight, as compared with the media now to be described. Transillumination of the stomach with quinine solution, however, gives much better results than with plain water.

2. *Horse-chestnut.—Æsculus hippocastanum. Cortex hippocastani.*—Native of Asia, now grown in Europe. See U. S. Dispensatory, 1900, etc. *Esculin*, a bitter principle obtained from a decoction of the bark. Space precludes a description of the process. The crystals are shining white, prismatic, inodorous, bitter, slightly soluble in cold water, more so in boiling water; soluble in alcohol and in alkaline solutions.

In France the fixed oil extracted by ether, has been administered in rheumatism, as has also a decoction of the bark. A decoction of the leaves has been employed in whooping-cough.

Esculin in gr. xv. doses has been given in malaria. It is therefore *safe* for internal administration. Morton and others have demonstrated its fluorescence with the X-ray. Morton states that an infinitesimal dose in an alkaline solution will fluoresce. One could use therefore gr. ⅛ to gr. ¼ esculin in a pint of alkaline solution (sod. bicarb. gr. xx. to gr. xxx. dissolved in one pint of water) as a fluorescent medium. Esculin, however, is practically impossible to secure at the present time, and Dr. Achilles Rose has suggested a decoction of the *fresh shells* of the horse-chestnut for the purpose of securing a fluorescent medium for transillumination. It is claimed that the American horse-chestnut possesses convulsant properties.

The most marked fluorescent medium with which I have thus far experimented is fluoresceïn (fluorescin).

3. *Fluoresceïn* (*Fluorescin,* Merck & Co. $C_{20}H_{12}O_5$) is manufactured from phtalic anhydride (a naphthalin product) five parts and resorcin seven parts, heated to 200° C. It is a red, or dark red powder soluble in alcohol, giving a yellow-red color and green fluorescence. It colors the cornea green, or rather fissures thereof, and has been employed by oculists to detect corneal ulcers. A solution gr. x. to ℥i of water containing sodium bicarbonate is non-irritant. The above is from the U. S. Dispensatory, 1900. I have so far been unable to obtain any literature, or further description of its properties from the manufacturers. Morton and other X-ray specialists have demonstrated its fluorescence. The above facts, I believe, are all that are known about fluoresceïn (fluorescin).

Therefore, before employing this preparation for internal administration, further investigation of its properties became necessary. The following researches were therefore instituted by me. The experiments with animals were conducted in the laboratory of the Physiological Department of Columbia University. I was assisted by Mr. J. T. Hoyt.

Experiment 1.—One grain of fluoresceïn (fluorescin) was added to 2 c.c. of 95 per cent. alcohol and to this was added 2 c.c. of sterile water. The fluorescin was partly dissolved and partly held in suspension. This was thoroughly shaken up and then injected subcutaneously into a rabbit. No symptoms followed. The animal was carefully observed for fifty minutes—conditions were all normal and at the end of this period the rabbit was as lively as ever.

Experiment 2.—Two grains of fluorescin were added to 12 c.c. alkaline solution. This consisted of sterile water in which grs. three sodium bicarbonate had been dissolved. Part of the fluorescin was dissolved and part was in suspension. The mixture was thoroughly shaken up and injected subcutaneously into a dog weighing about 20 pounds. No symptoms followed. For a short time the animal apparently had some local discomfort from the amount of fluid injected, but this soon disappeared. The dog was carefully watched for forty minutes, and all conditions were perfectly normal. These animals were kept under observation for twenty-four hours and a careful examination was then made. There were no evidences of swelling, or irritation at the seats of hypodermic injection, and the animals appeared normal in every way. During this period there were no symptoms whatsoever.

On the strength of these experiments, I took a small quantity of fluorescin internally—about gr. ¼—without any discomfort. The facts that small animals such as rabbits and dogs experienced no discomfort from hypodermic injections of one to two grams, also that it is non-irritant to the eye, were sufficient evidence of the safety of its internal administration.

In order to obtain the best results with fluorescin for transillumination of the stomach, it was deemed necessary to further investigate its qualities, the proper quantity to employ in order to secure maximum fluorescence and the influence of hydrochloric acid on the medium.

To Mr. F. N. Ferry, the chemist of St. Bartholomew's Clinic, I am indebted for valuable assistance and suggestions in the following experiments. He called my attention to the value of glycerin to increase fluorescence, and together we conducted experiments in the clinic laboratory. (1) Employing from gr. ½ to gr. i of fluorescin in an alkaline solution of sodium bicarbonate; as we increase the strength of the solution, fluorescence diminishes and colorization of the solution begins and increases. Greater strengths than these, color the solution still more, with diminution of fluorescence. Pint solutions were employed in all cases, as this is the average quantity used in transillumination of the stomach. (2) Gr. ⅛ to gr. ¼ fluorescin in a pint of alkaline solution (water containing grs. xx-xxx sod. bicarb.) gives marked fluorescence; is a fairly alkaline reaction; (3) fluorescin is only *slightly soluble* in plain water and gives

a *neutral* reaction with litmus paper, and there is hardly detectable fluorescence with the medium; (4) fluorescin gr. ⅛ with grs. xx-xxx sod. bicarb. in a pint of water plus ʒi glycerin, fluorescence more marked than in (2). Ferry has demonstrated that the addition of glycerin increases fluorescence. If we add another dram of glycerin, fluorescence increases somewhat.

Since the stomach is an acid medium and fluorescence acts best with fluorescin in an alkaline medium, it became necessary to experiment with hydrochloric acid: (*a*) Water one pint in which sod. bicarb. grs. xx, one dram of glycerin and gr. ¼ fluorescin are dissolved; to this add one dram of acid hydrochloric dilute, and fluorescence nearly disappears. On the addition of sod. bicarb. grs. xx fluorescence returns. (*b*) If the original solution contains grs. xl sod. bicarb., and then add one dram of acid hydrochloric dilute, the reaction remains alkaline and fluorescence persists. These experiments further demonstrate the fact that an alkaline medium must first be administered to the patient, and this is to be followed by an alkaline solution of the fluorescin.

Having noted that Hammer, Tracy, Morton and others suggest the administration of radio-active water as a therapeutic agent, and, furthermore, that Morton states that radio-active solutions increase fluorescence, I was the first to suggest to Dr. Morton the *addition* of *radio-active solutions to a fluorescent medium* for the *purpose of transillumination of the stomach.* As soon as a perfectly safe radio-active solution can be secured he has agreed to demonstrate the method at my Ward's Island clinic.

Since Tracy states that radio-activity is well exhibited in normal saline solution, as a preliminary investigation, I tried the effects of normal saline solution with fluorescin. (1) Normal saline solution one pint plus ¼ gr. fluorescin—alkaline reaction, slight fluorescence. (2) To the same solution add grs. xx sod. bicarb. and fluorescence increases; (3) add to this one to two drams of glycerin and it increases more rapidly and markedly; add one dram of acid hydrochloric dilute and fluorescence diminishes somewhat. Then add grs. xx sod. bicarb. and fluorescence increases.

We have, therefore, ready for further experimentation a fluorescent solution suitable for displaying radio-activity. Accurate investigation into the degrees of safety of the latter and not mere theorizing is now necessary, before employment of the radio-active solution. The saline fluorescent medium itself is perfectly safe. Finally further careful experimentation developed the fact that gr. ⅛ of fluorescin to the pint of alkaline solution with a small amount of glycerin, gives the best results.*

Recently at my Tuesday Clinic at the Manhattan State Hospital, West, Ward's Island, the method of transillumination of the stomach with fluorescin was performed on two patients in the presence of Dr. Achilles Rose and other physicians. The results were the most satisfactory that I have ever seen, and I believe that in this we have so far the ideal method of stomach transillumination. Absolutely no disagreeable results in any way followed. It is unnecessary to aspirate out the fluorescent medium, unless the Rose's belt is to be applied, in which event it is preferable, as it is more comfortable for the patient. Two patients have recently been examined at the Manhattan State Hospital, East, Ward's Island, by the same method and with success.

The method is as follows: The patient is given a glass of water (eight ounces) in which xv to xx grs. of sodium bicarb. are dissolved to neutralize stomach acidity. This is then followed by another glass of water (eight ounces) in which are dissolved grs. xv-xx sod. bicarb., one dram of glycerin and gr. ⅛ of fluorescin. The patient is then taken into the dark room and the Lockwood electric light (gastrodiaphane) is introduced like the stomach tube. This instrument is extremely small, gives a brilliant light, and when manipulated in the stomach hardly ever gags the patient. A certain amount of manipulation is necessary in order to determine the lower margin of the stomach at the point of maximum intensity of the light. By pressure on the abdomen and manipulation in forcing the light into the organ for the full length of the carrying tube, the lower border can be accurately located. Moreover, manipulation is at times necessary to determine the relations of the lesser curvature to the diaphragm, a point of differential diagnosis between simple dilated stomach and gastroptosis. With the new method of transillumination with fluorescent media, especially with fluorescin, this is generally unnecessary, and comparing the results with those of water, as formerly employed, I believe the improvement to be marked as well as a scientific advance. The differentiation of tumors of the stomach, liver and intestines is rendered easier, I believe. As far as I have been able to investigate the literature, I cannot find that this method of transillumination of the stomach has been heretofore employed.

Before concluding, there are other qualities of fluorescin which I should mention: (1) The fluorescence of the prepared medium increases, the longer the exposure to light; hence it is advantageous to prepare the solution half an hour or more before use, though this is not necessary; (2) the powder is so extremely light, that powders of gr. ¼ can readily be made up and these easily subdivided into gr. ⅛ at time of use; (3) the fluorescent medium leaves a slight yellow-red stain on the hands which can be readily removed.

In conclusion, let me say that there are certain interesting problems that suggest themselves to us from this work: (*a*) The use of a radio-active solution in the fluorescent medium for stomach transillumination; since Morton demonstrates

* By recent experiments I find that lime water ʒij may be administered in each glass of water, as a substitute for the soda bicarbonate. Laparotomy on a case of gastroptosis transilluminated with fluorescin at the West Hospital, has recently demonstrated the absolute accuracy of the method.

that a radio-active solution increases fluorescence; (*b*) the radio-active solution in the fluorescent medium might itself give us a picture of the stomach in the dark room, by use of the fluoroscope alone. (*c*) The possibilities of thus photographing the stomach either with or without the accessory of the X-ray apparatus, by using the radio-active solution with fluorescence internally.* Fluorescin, as I have demonstrated, combines well with a normal saline and soda solution. (*d*) The possible value of the non-irritant fluorescin solution in the bladder, for the purpose of improving the scope of cystoscopy and an investigation as to whether such a solution would enable us to detect minute ulcers, or fissures in the bladder, just as in the cornea.

Whether fluorescin has been given for therapeutic purpose, I cannot state positively, though so far I have been unable to find any record of the same, nor had its manufacturers any record of its internal administration, as I have heretofore stated. I trust, however, that these researches and suggestions may prove to be of some value to the profession.

107 East Fifty-seventh Street.

THE SCOPE OF PHYSICAL ECONOMICS: AN INQUIRY INTO THE POSSIBILITIES OF ENHANCING HUMAN EFFICIENCY THROUGH PHYSICAL EDUCATION.†

BY J. MADISON TAYLOR, A.B., M.D.,
OF PHILADELPHIA.

The term physical economics, as used here, is intended to embrace the principles through which are to be acquired normal motor energizing, also functional balance, and are essential to bodily and mental well-being. It is an axiom that complete mental energizing is conditional upon adequate physical functionation. The term adequate is used because perfect functionation is not always to be expected, but enough is an elemental requirement. One or other item, or degree, may be lacking, but the norm for the individual must be attained, or maintained in order to preserve intellectual equipoise and practical efficiency. It is a rule, accepted on all sides, that mental balance can only be preserved through a persistent attitude of deliberate watchful control of all the powers. Enough, perhaps, has been said to emphasize the paramount importance of "equanimitas," the serene intellectual attitude most needed in all human effort. Those who have recognized this truth have numbered among themselves the great ones of the earth since the dawn of history.

There have been times, protracted periods, when little attention has been shown in that even greater theme, greater because a primordial necessity, of bodily equipoise through which alone the superior intellectual processes can thrive.

The teachings of physicians deal over largely with the mitigation of ailments, derangements and diseases. Preventive measures have never, not even now, attained the recognition they deserve. To conserve and amplify bodily forces is a pursuit justifying the best attention of all physicians but fails to receive its desert. The church has persistently magnified the Spirit at the expense of the body in all ages; and left an indellible mark, especially on the history of the Middle Ages. Yet a clean body, free from grossness, is needed for a pure spirit. Mere Animal vigor is not what is occupying our attention here. Meanwhile the growth of a movement to place a just appreciation on bodily conformation and well sustained vigor is assuming large and praiseworthy proportions. This movement is healthy and to be encouraged but is, as yet, a mere revolt at worse conditions or restrictions and requires careful guidance. It is worthy of the best attention, the most unremitting study of scientific and benevolent men, who are the only suitable teachers and guides. The awakening of interest in acquiring bodily perfections has begun chiefly among those who are moved more by the stirrings of primordial physical instincts, of mimic war or sports imitative of human struggles, hampered by human passions and appetites, than from a wholesome appreciation of the largest ultimate good. Hence we see vast multitudes sit spellbound at exhibitions of warlike contests on athletic fields, on water sports, on pageants reflecting war or the chase, or even at prize fights, than can possibly be collected, or held, by the exhibitions of artistic, scientific or intellectual men, their preachings, or products.

Hence in the growth of that interest now so widespread in the betterment of individual vigor the movement is reflected chiefly from the athlete and the professional competitor.

The teachers and (*mirabile dictu*) the writers on physical culture, are composed largely of those who have gained fame as wrestlers, prize fighters, track athletes, fencing masters, and professional trainers or teachers of such matters in the army, drill sergeants, and in colleges, performers on the stage and the like. We can learn much from these men; they furnish a sound, practical basis of principles upon which success has been gained and laurels won in many departments; many of these are well worthy of imitation, it is true, but they often make statements requiring the most careful revision by the educated physician. Just here is pertinent to remark a curious fact, that although the semiprofessional teachers in colleges, the coaches of the baseball and football teams, the track athletes, the oarsman, etc., are often graduates not only of the colleges, but also of the medical schools, they have as yet added little to the literature of physical economics. They are the men who

* By further investigation, I have not been able, so far, to arrive at a positive conclusion that the addition of a radio-active solution to a fluorescent medium at all increases the intensity of the light in transillumination of the stomach. Dr. Sinclair Tousey has photographed for me the stomach of a rabbit filled with radio-active solution combined with fluorescent quinine solution; Medical Association of the Greater New York, March 14, 1904.

† Address delivered before the Association for the Advancement of Physical Education, at New York, Jan. 16, 1904.

ought to act as guides to youth. So far they have done nothing commensurate with their opportunities.

Fortunately, the subject is becoming amplified by the formation of associations composed of those who undertake the scientific pursuit of physical advancement or who have ranged themselves in the rank of lovers of the ideal man or woman, and from their individual and joint efforts and the frank discussion of expressed opinions much true progress may be expected. For them the watchword must ever be high ideals and critical investigation.

The best work can be done by those who have had a thorough medical education, or at least a full knowledge of anatomy, physiology and anthropology. In the absence of such groundwork false conclusions are likely to be reached; errors various and disconcerting will be made. Certain individuals of my acquaintance, non-medical, have taught me a great deal of value; many special "courses" have I taken, hoping greatly but rarely learning much. Occasionally the light is flashed here and there on new realms of thought. We are still on the threshold and must win our way by honest individual and mutual self searchings.

Let me offer a few thoughts on those salient, or rather fundamental, principles, which seem to constitute the objective points of our search. A wise friend, not long since, in a discussion of things grave, expressed his surprise that the one distinguishing quality or attribute of Christ had, so far as his researches taught him, been overlooked. This is poise, which may be described as the maintenance of a justly proportionate energizing of all vital forces of body, mind and Spirit.*

The divinity of Christ was enshrined in a human organism of perfect proportions and powers. We need no better proof of this assumption than is afforded by the description of His life and human acts as recorded in the Gospels.

The material part of Him could obviously sustain no improvement. No one can read the Gospels, as a believer or skeptic, and fail to note his splendid symmetry, reserve power, coordination of mind and body; in short, his perfect poise.

So it is that man, in whose image he is clothed, can do no less than strive to acquire so much of similar perfectness as his individual endowments enable him to attain. The word, then, which more nearly describes the physical and mental completeness of the perfect man, is poise. It should be our aim to secure this attribute for those in our keeping. By this standard alone we measure fullest human efficiency.

In estimating the factors which make success, and providing standards, let us leave out always the extreme types of superiority, the product of reprehensible specialization such as the triumphant financier or champion prize-fighter.

It is our prerogative to equip the individuals in our keeping with the highest vital dynamics. To do so, it is imperative to assume an ideal toward which always to strive. This ideal should be understood and defined as fully as possible. The qualities we desire to confer should be formulated accurately in our own minds. In our solution of the individual problem full consideration must be given to age (actual or relative), sex, antecedent history, vital resistance, constitutional or acquired weakness or damage, social or racial habits, and, above all, a study of temperament.

We are called upon, perhaps, more often to improve the bodily condition of those who are of fairly good constitution and relatively young, but full grown. The very young are, or should be, under school trainers who need all the wisdom possible, as theirs is the opportunity of molding during the period of plasticity.

Our first consideration should always be to search out the acquired faults of posture, limitations in range of movement, the coordination disabilities, to note short comings in symmetry, in hypertension or overrelaxation and all developmental defects. We should always define the equation between the force and accuracy of voluntary and involuntary acts, and determine whether less or more are required to accomplish desired results. Some people, indeed, the majority, fall early into habits of inaction, involving if not the whole, then some considerable part of the body, through which a large train of degenerative phenomena arise in certain tissues; others, and many under emotional strains, exhibit a prodigality of action most wasteful of nerve force and are thus constantly on the verge of exhaustion. The value of the exercise of economy in vital forces is fully appreciated by drivers of draught animals, by athletes, and the employers of labor in all fields.

Some men and women who assume heavy responsibilities are fully alive to this elemental economic principle also for themselves; but, alas, too many do not appreciate the individual application. In proportion as they learn this truth, and act upon it conscientiously, they become and remain efficient.

What profits it if one shall become a great power for accomplishment, in some special direction, if he lose health or capacity for sustained effort? This problem of the relationship of work to the capacity for effort and its corollary nerve tire, is of deep importance and my teachings in this line are on record. My thesis is the scope of physical economics and the central thought of mental and physical poise must never be lost sight of in aiming at consummate fitness. In acquiring poise the perfect adjustment of effort in any direction to result or product we must first consider early development, next, middle age development, and finally, the reacquirement of so much of our latent capacities as is possible, consistent with the age reached and the disabilities already accrued. Herbert Spencer makes the assertion that the marvelous motor and sensory acumen of the Indian hunter, trained from childhood in observation, in patience, in niceties of physical and mental adjustment, required by a

* This observation is confirmed by several learned clergymen.

struggle for existence in a primitive state of society, can never be paralleled by any imitation. All this is true, but it is also true that higher intelligences, as found among Circassians, are capable of special training and adaptation which can, and do, equal the physical powers of the Indian in most particulars and excel in some.

A thorough education of the central nervous system, the foundation of sensory and motor training especially during the period of plasticity, is an absolute essential to the attainment of even relative perfection in any line.*

It must not be overlooked, however, that immense advantages follow efforts to develop dormant powers late in life. The whole progress of ageing is one of development. Only toward the end of a long life in one structurally sound can the phenomena of decadence be said to arise, and even then the tissues are capable of much wholesome modification. Old people are susceptible of decided physical improvement by systematic attention. It has frequently happened in my experience that an elderly person seeks advice for obtrusive evidences of weakening which brings to notice the fact that, while pursuing life's work, specializing possibly in intellectual directions, no commensurate care was taken to maintain the body in proper standards of excellence. Providence is trusted contentedly to continue his gifts of physical health. Meanwhile no effort may have been spared by the individual to bring the mental powers to the highest plane of efficiency. Under the age of seventy years, it is usually possible to find a virgin field for improvement. After that period much can still be accomplished. Often in those who distinctly evince a diminution of vigor not only can extraordinary rejuvenation of physical powers be enjoyed, but, as the structures regain lost or previously developed tone, the blood and lymph being purified and oxygenated by stretching movements, many cells long suffocated become alert, and a new order of things arises in mind and heart. The stream of life flows more clearly, more cheerily, no longer the muddy current, the offensive stagnant pools. All nature takes on new colors, new shapes, and, above all, new hopes and capacities for enjoyment awakened.†

Again, let us consider those persons who have suffered some grave organic damage of lung, kidney, heart, digestive organs, nerves and the like. The time was, not so far away, when for these the fiat went forth that such sufferers must content themselves to be set apart, to live a life limited to fewest activities.‡

In all these and many more conditions of seemingly irrecoverable organic disability, it must be remembered that the best form of movement cure is that which is made by the physician pulling and rotating. This much-neglected passive education, even in those capable of much activity, admirably furnishes training for the joints which are thus reset and remobilized, venous and lymph stases are relieved and great comfort is afforded to many forms of disability, large and small. The physician should begin, and himself apply much of the passive movements in many instances. There is still an ample field for the skilled masseur.

The scope of physical economics can scarcely be bounded. Thoughtful men, medical and lay, will develop the theme increasingly, each according to his taste, capacities and originality. Certain definite principles must govern. It appears to me a few objects and standards of excellence should be formulated. The primary aim should be to acquire right posture. There may be differing opinions as to what this is, but a suitable model is a youth, or a maiden, of about ten or fifteen years, untrammeled by costume or occupation deformities, and the product of freest opportunities for physical activities, where the stimulus of most varied effort is duly modified by the overcoming of difficulties.

Again, whenever contractures, due mainly to hyperconsciousness or asymmetrical tensions, confining occupations or disease have marred the organism these must be corrected and removed. A point which impresses me as of vital importance in the performance of all regulated movements, is deliberation and accuracy, with intervals of complete relaxation. Rapidity is sometimes called for, of course, but rarely, and should always be subordinated to nicety and precision. Action, to fulfil these requirements must be by an organization whose parts, both the central and peripheral, are in normal adjustment. Whenever it seems to be otherwise, the inevitable conclusion follows that with improvement in adjustment an amplification of efficiency will follow. Again, in the performance of evolutions, single and complex, the best single principle of action is the parabolic increment of intensity from lightest poise to fullest tension, such as the exquisite elaborate action of the fencer's thrust. A very brief period of exercise daily, augmenting extensor action for the arms and flexor action for the legs; repeating accurate movements, normal in direction always, but of the widest variety, each act as a geometric increment from poise to complete contraction, will do more to regain symmetric tone and educate motor centers, in brain as well as muscles, than hours spent in dawdling field sports.*

For the remedying of a vast array of disabili-

* This topic has been ably treated by Prof. Halleck, of Yale, in a small book which is not too elementary for anyone to read with advantage.

† See paper by this author: "Conservation of Energy in those of Advancing Years," in the Popular Science Monthly, Feb., March and April, 1904.

‡ The author read a paper at Washington on the treatment of chronic heart disease in children by regulated movements. In the discussion little encouragement was meted to his views. One of New York's most distinguished masters in medicine declared such opinions dangerous or worse, yet, some before and many since, have advocated carefully supervised activities for those of damaged hearts. Some risks may possibly be run, not grave ones; but consider on the other hand the deprivation of rational pleasures thus imposed; the rapid degenerative changes following in all organs, if the blood stream is not encouraged to become freshened by natural outlets of energy. The author's earlier days were spent in the office of the greatest neurologist of America, a man who is wiser than his colleagues in recognizing the efficacy of passive and active movements, yet for years the opinion prevailed even with him, that locomotor ataxia should be treated by almost absolute rest. Now Fraenkel and others have specified certain active exercises for this disorder as necessary to recovery of health.

* No disparagement is intended of the utmost utility of field sports

ties, large or small, in old or young, in brain workers or in laborers exhausted by monotonous physical toil, no agency is capable of affording so much relief as a scientific application of the broad principles of physical economics.*

Many of those who consult the physician describe themselves as fairly well but easily fatigued by slight exertion; in fact, while far from strong, they are free from definite organic disease. The custom is to treat such folks by rest, extra care as to exertion or exposure, tonics and forced feeding. A large proportion of these disappoint both us and themselves, remaining below par indefinitely after having exhausted the resources of more than one excellent medical adviser. Even when certain organs are deranged, or convalescing from acute disease, many of these people will recover entirely and promptly, provided the motor activities are called into use in such a fashion as shall encourage a return of full circulatory balance, not only in tissues and organs disturbed, but also by restoring the normal circulation in these segments of the cord whence they are innervated.

In short, scientific medicine, working with all its resources at command, often reaches the limit of progress toward health. Then, if we have recourse to the possibilities of what may be termed physical economics, large, timely, and often unexpected gains can be made. Practical physical economics may be described as a scientific study of the normal bodily movements in direction and force and employed in such a fashion as shall best supply the needs of the organism, holding in careful consideration the disabilities present, using only those measures and so much of them as shall be admissible, and increasing them wisely in force, repetition, frequency and breadth as shall secure the desired results.

This work cannot be delegated by the physician to any other person; he should be the one to determine the manner, and amount of such activities based upon his knowledge, first, of the natural history of disease, and second, of the possibilities of tissue activities, normal relationships and coordination, and third, a careful estimate of the defects in original development of the patient and the acquired deformities. When the problem has been outlined from adequate knowledge of both suitable standards, and a formulation of the special needs and possibilities of the case, it will be found that not only can results be secured far in advance of the ordinary methods employed, but that the scientific resources of the physician are by this taxed quite as fully. The reason why physical readjustments and restoration by passive and active manipulations, and reeducation in normal activities are held in such small esteem by the profession is plain. The fact is, that few physicians know anything about the matter and are disinclined to learn, contenting themselves in covering up their ignorance by belittling the value of the subject. Their interest may have at one time been aroused in allied subjects, or if still extant, usually takes the form of mere amusement in certain forms of athletic games or sports. In these they acquire a superficial familiarity, but rarely give their attention to those fundamental laws of the motor activities which would fit them to act as guides or experts. They do not understand what the body is capable of, hence they cannot know how to restore its powers. A few are aware that something of value can thus be accomplished, but, conscious of their shortcomings, employ one sort or another of physical trainer through whom probably more good is obtained than harm wrought, but it is a slipshod method at best. Even the orthopedic surgeons, to whom problems of advanced deformity are sent, rarely realize the fundamental problems submitted and content themselves with routine procedures applied by hirelings, not medical experts, and the use of supports and corrective apparatus, the cutting of tendons and other operative measures.

By far the larger number of those for whom corrective exercises are needed either go without or seek on their own recognizance various self-styled physical culture experts and thus often secure much betterment but oftentimes some harm, and rarely get what they actually need. If one will reflect a moment and take a broad view of the subject of physical efficiency it will be patent that we are now in a transition stage which must be followed by a fuller realization of the gravity of the problems involved. It is possible to demonstrate the fact that the scope of physical economics is vast and of vital importance, but practitioners of medicine have been curiously indifferent.

A consequence of this is that the public fails to regard medical practitioners as authoritative in a broad field of influence and, becoming aware of its needs, seeks advice at the hands of bold claimants who strive to justify their assertion that by regulated exercises and manipulations an enormous array of discomforts and disabilities, both minor and major, are relieved or cured. Thus is medical potential lowered, respect for the resources of medical art is lessened, and much harm done to the esteem which should be our prerogative. If the profession generally cannot, or will not, realize the gravity of this position and study this clearly definable branch of therapeusis, at least they could encourage a few to make it a specialty and give them the cooperation extended to the well-recognized forms of specialization and accord them the same trustful mutual interchange of courtesies. If not, then much work which could, and should, be done by skilled physicians will drift off to irregular practitioners who are not slow to sneer at our limitations.*

as occupying time and supplying motor coordination, air and sunshine; but form is here required to get the best personal results.

* Not the least utility of the teachings of physical economics, is that which accrues to the teacher. Attention along wholesome lines is retroactive and makes for his or her betterment. It seems to me the plain duty of the experts, is to embody in themselves the principles taught. His or her person should stand as an example of complete poise and be made to improve steadily as time progresses, and serve as a constant evidence of the conservation of values.

* See article by the author, "Remarks on Mechano-Therapy, Bone Setting and Osteopathy," New York and Philadelphia Medical Journal, Dec. 16, 1903.

Let me make a few remarks which will serve as the equivalent of case citations and then proceed to offer a few fundamental principles of physical economics.

It would seem that among children few instances occur requiring systematic readjustments, unless from the effect of congenital or profoundly disabling disease, yet my experience for many years has led me to recognize and correct many minor disabilities and to train these folk into efficient individuals. Small defects, arising during the plastic years, readily grow into larger ones and are only too rarely "outgrown" spontaneously. It is my pleasure to feel I have deflected much material from future orthopedic clinics by correcting deformities in their incipiency. By this means also organic maldevelopments are saved, especially of the lungs and heart which are dependent for full capability upon a roomy elastic thorax. Many organs are subject to mechanical disabilities in the abdominal cavity where a brace in time may spare many ptoses. These ptoses, relaxations and displacements of the abdominal organs are now recognized to be both numerous and significant. Most of these are distinctly more preventable than curable. The prevention is easy by conferring normal tonicity upon the supporting tissues, and the fundamental requisite is symmetric central vigor and elasticity of the skeletal structures. Again, a vital requisite is full lung competence; in feeble children or others unable to take adequate exercise the lungs fail of full expansibility. By breathing exercises and by developing the elasticity of the thorax, arms and shoulders great gains can be made and the capacity of oxygenation amplified. Again, for a long time I have treated many organic troubles in children, even those of the heart, by regulated movements as stated before, by which compensation is much earlier obtained. By passive followed by gentle active movements much discomfort is saved to the cardiac sufferer, passive congestion relieved, organs and muscles brought to a higher state of efficiency, and the joy of vegetative existence increased. Often fuller activities are made possible. In short, the poor disabled creature is invited to become a part of the scheme of life, not a mere incubus or excrescence on the body politic.

No effort can be economically expended without the compensatory action of relaxation, by periods of complete rest, or cessation of voluntary action. These intervals of rest to be effective must be as nearly absolute as possible, and of much longer duration than the time occupied by tensions.

It is a prerequisite condition of motor efficiency to acquire full power of complete relaxation, and must be the first qualification striven for. This accomplishment, once acquired, will fit one to immeasurably save nervous force for expenditure in specific directions and to secure the largest results.

If tension be maintained for a moment longer than is needed the reserves of energy are being squandered. This prodigality of energizing may be expended consciously, but far more frequently without being recognized. In most of us, especially those who are overenergetic, high strung, intense, it is an unconscious attitude, a bad habit which should be sedulously overcome. Among the weak and neurasthenic it degenerates into fidgetiness. Those enviable beings who possess a placid, calm disposition, an imperturbable temper, are always in a position of advantage over others whose reaction time is excessive.

However, it is entirely possible for all of us to imitate them and acquire some degree of this control over our ebullient forces. In proportion as we learn to relax, do we save not only our physical reserves, but improve our accomplishments.

The attitude of physical relaxation is the starting point for all effort. Again, the consequences of overtension result in rigidities and contractures. They are to be found in nearly every human being, old or young, beyond early childhood. The causes are chiefly hyperconsciousness, but others are old toxic irritations, as of gout, fibrositis, rheumatism, the infections, and any irritant reacting on the centers of nervous force.

These tensions, and the resultant contractures, are hurtful for several reasons. They cause continued pressure upon delicate structures such as nerves, blood vessels, and lymph channels by muscle masses and other structures which have become rigid. Cellular interchanges are thus impaired; organs of special sense, as the eye, the ear, and the structures of the throat and nose, all thus frequently suffer structural damage or functional impairment. It is common to find in one who suffers impaired functional competence of one of these organs as of the heart or circulation of the brain, such as headache, vertigo, confusion, insomnia and the like, abundant evidence of rigidity in the tissues of the neck and extrascapular tissues. When the rigidities are removed it frequently happens that these disabilities are often entirely removed. Scores of cases could be cited where the sufferer had employed the best specialists and been for years under the care of leading neurologists—still unrelieved.

The objects to be obtained are plain; these are to acquire elasticity of these hardened tissues, and a capacity to relax. To do so involves careful teaching by one who appreciates the situation and has a practical knowledge of the normal states and capacities of muscles and ligaments. It is accomplished chiefly by passive movements and manipulations and partly by judiciously directed active movements.

To acquire normal attitudes it is absolutely essential that symmetrical elasticity of the tissues be first secured.

Relaxation being gained, or fully appreciated, the principles of physical economics may be outlined as follows:

1. *To acquire normal attitudes.*—Few persons are free from local or general faults of posture and most have acquired deformities.

2. *To overcome contractures.*—It is rare to find one who possesses perfect mobility of limbs, or neck, or other frequently used voluntary muscles, and it is exceedingly common to find the less used joints grievously stiff and contracted, especially the hip-joint and the junctures of the ribs, the origin and insertion of many muscles, deep-seated tendons and ligaments.

3. *To attain full flexibility of the muscles by which alone their competence is established.*—Here relaxation is an imperative condition. Also steady stretching is most effective, protracted till the tensions are overcome, or taught to overcome themselves.

4. *To acquire accuracy in movements.*—Along with deliberation graduated increments of force should be employed, particularly in extensions, which should be from full relaxation in a parabolic curve of force to the perpendicular of extreme tension. This is the chief index of power and on this basis alone is economy of forces to be estimated and conserved. After accuracy is attained speed may follow and then be of some utility. It is desirable also to secure:

5. Full capacity for extension, first passive, and later active, by which the tendons are stretched to their uttermost and through this much improvement is possible, not only in the efficiency of the muscles but also reflexly in the nutrition of the centers, is enhanced.

6. Full respiratory capacity; the basis of oxygenation in lungs as well as muscles. This may be acquired by systematic breathing, rhythmic inspiration and expiration, both increasingly, until by securing invigoration of the thoracic tissues, supplemented by the abdominal muscles and especially the diaphragm, not only is full forced inspiration accomplished, but, of equal importance, fullest expiratory emptying of the lungs. This should expel the last possible remaining complemental air from the recesses of the lungs and greatly enhance the interchange from the residual air.

7. Circulatory capacity, the heart and great veins need development; a long story and attainable through automatic movements repeated to the limit, or by movements of skill, training, balance, accuracy, variety, etc.

8. Capacity for muscular endurance, by repetition of automatic simple acts or variegated movements, such as in fencing, the various games of skill, tennis, squash, handball, etc.

9. Muscle building; of little or no use to those not young or fairly vigorous, but of great importance to those who are markedly weak at any age, provided there is no contraindication.

10. A combination of muscle-building accuracy, endurance, full muscular competence of limbs and heart from such means as fencing, wrestling, boxing, or other dual contests.

It is usually sufficient for any one who desires to pursue physical economics for the purpose of acquiring full bodily efficiency, short of competitive athletics, to work mainly for elasticity and accurate tensions.

MEDICAL PROGRESS.

MEDICINE.

Mathematics of the Diabetic Diet.—That in most cases it is unnecessary and superfluous to entirely withdraw the carbohydrates from the diet of diabetic patients, is the claim made by A. C. Croftan (Jour. Am. Med. Ass'n, March 26, 1904). It is almost impossible to adequately nourish these patients unless the carbohydrate is replaced, bulk by bulk, by other food equivalents. The complete withdrawal moreover of the carbohydrates eminently favors the development of acidosis and precipitates the inevitable consequence of the latter, —diabetic coma. The author claims that mathematical accuracy should govern the regulation of the food of these patients. A normal adult requires from 30 to 35 calories a day per kilo of body-weight and if this caloric value is not supplied, the body must consume its own tissues and suffer accordingly. Where there is a loss of sugar in the urine the average diet will not furnish the required caloric value. By knowing the daily amount of sugar excreted, it is possible to estimate what proportion of the deficit is made good from the patient's tissues and the diet regulated. It is necessary in each case to determine the tolerance to carbohydrates. Occasionally the sugar is due to too much sugar in the food, but generally to insufficient power in the organism to destroy the normal amount. There are three degrees of glycosuria. One may speak of the mild form, if the sugar excretion stops at once after the withdrawal of the carbohydrates, if it does not reappear when small amounts of the carbohydrates are again administered and if at no time the amount of food albumin need be reduced. In the medium form not only must the carbohydrates be withdrawn completely before sugar excretion ceases, but the food albumin must also be reduced to such a point that less than 18 grams, but more than 10 grams of nitrogen appear in the urine. In the severe form, in order to stop the glycosuria, the carbohydrates must be stopped, and in addition so much albumin must be withdrawn, that less than 10 grams of nitrogen appear in the urine. The diet ordered must therefore maintain the nitrogen equilibrium; *i.e.*, the nitrogen output must never exceed the nitrogen intake. The patient therefore must receive food that, after the deduction of the sugar wasted in the urine, allows him to utilize at least 35 calories per kilo of body-weight pro die. The author considers however that in certain cases it may be well to give a certain amount of carbohydrates even though the sugar does not entirely disappear, viz., (1) the impossibility of adequately nourishing most patients on a meat fat diet alone, and (2) the increased danger of acidosis and coma incident upon the entire withdrawal of carbohydrates. It is advocated that the diabetic be treated for a time at least in some institution where the case may be studied as outlined above, and the author also decries the method so widely adopted of handing every patient with sugar in his urine, a diet list on which is to be found a list of articles that contain no carbohydrates.

Diagnosis of Pulmonary Insufficiency.—If the examination of a heart case is begun with auscultation, pulmonary insufficiency will often be mistaken for aortic regurgitation since the maximum murmur of the latter is often situated over the pulmonic area. E. Fromherz (Münch. med. Woch., March 8, 1904) auscultates last of all and thus avoids the common error. The absence of the typical appearance, with the peculiar pulse, the retinal pulse and the downward enlargement of the heart so common in aortic disease will make a pulmonary insufficiency very probable, even if auscultation detects a murmur characteristic for the former. In addition, the

right ventricle is considerably hypertrophied. When complicated with stenosis, the second pulmonic sound is weak or absent and the patients are very cyanotic; the prognosis here is very grave. In persistent ductus Botalli the heart is also enlarged to the right and a systolic murmur is also heard over the second or third left interspace, but this murmur occupies only the second part of the systole. It is well demarkated from the second, accentuated sound and as a rule the first sound can also be heard; sometimes the second sound is accompanied by an inconstant murmur. No difficulty is usually experienced in differentiating from pericarditis or from extracardial murmurs such as occur with typhoid, rheumatism and chlorosis. In severe cases of mitral stenosis, a relative pulmonic insufficiency may occur and very rarely both aortic and pulmonary valves are diseased.

Typhoid Bacilli in Urine and Feces during Convalescence.—The occurrence of virulent typhoid germs in the urine and feces of convalescents from typhoid is of the greatest importance in the prophylaxis of the disease. According to D. HERBERT (Münch. med. Woch., March 15, 1904) the urine is a greater source of danger than the feces, since bacilli were found in 18 per cent. of the former and in only 3 per cent. of the latter. The last positive cultures were obtained in from eight to twenty-seven days after the cessation of the fever, the average being fifteen days. With one single exception the excreta were harmless during the second month of the disease. The technic is very simple: a small amount of the fresh urine or stool is simply plated on the special medium of Conradi and all suspicious blue, glassy colonies are tested for motility and agglutination. The appearance of the colonies alone will often warrant a diagnosis.

Influence of Hydrochloric Acid on Pepsin in Stomach.—If a dilute solution of hydrochloric acid is introduced into the stomach, a large amount of the fluid, still of high acidity can be expressed after one-half to three-quarters of an hour while the same amount of water without acid will have disappeared in this time. According to A. HEICHELHEIM and M. KRÄMER (Münch. med. Woch., Feb. 23, 1904) the acid has a pylorospastic action which is most marked in hyperacidity and absent altogether in achylia when the contents of the stomach are very rapidly emptied unless stenosis or atony is present. In carcinoma of the stomach with absence of free hydrochloric acid a small amount of pepsin could always be detected after a simple test-meal, but a larger amount was always found if hydrochloric acid was first given, as this converted the pro-ferments into ferments. The same was also observed in achylia without carcinoma but to a much less degree and in a few cases with complete absence of pepsin, the acid had no effect. In normal cases the amount of pepsin was generally diminished if the test-meal was preceded by acid since this brought about an extraction of the gastric mucous membrane. In some cases of cancer, the expressed acid contained blood where previous test-meals had always been free; since this was never observed in simple achylia, it may help to a diagnosis where a palpable tumor is not present.

Typhoid Agglutination in Jaundice.—The fact that the blood of jaundiced patients will occasionally agglutinate typhoid bacilli, has considerably diminished the value of the Widal test. Though many such observations are on record, a true explanation of the phenomenon has not yet been given. Taurocholic acid seems to be the only constituent of bile which occasionally causes clumping but negative results are obtained with the blood-serum of patients treated with this substance. In the following cases M. STEINBERG (Münch. med. Woch., March 15, 1904) found agglutination in a dilution higher than 1-40: six of catarrhal jaundice, two of cholelithiasis, four of tumor, one of acute yellow atrophy, one of sepsis and one of febrile icterus; very high values were, however, obtained only where the patients had had typhoid some years ago. It is most likely that the jaundice itself is not responsible for the agglutination but the bacterial infection which exists in most cases of icterus. Typhoid bacilli are not only agglutinated by typhoid serum but also by the serum of patients differing from paratyphoid, colon, proteus and even staphylococcus infection. It certainly seems more plausible to accept this as explanation than to assume that disturbance of hepatic function so alters the blood-serum that it assumes agglutinating properties.

Urine in Lead Poisoning.—In a large number of cases of chronic intoxication with lead K. KLIENEBERGER (Münch. med. Woch., Feb. 23, 1904) invariably found elements pointing to a nephritis. The frequent presence of granular renal epithelium and typical granular casts with only few leucocytes and red cells seems to be characteristic for the acute phases of chronic saturnism so that a parenchymatous nephritis must be assumed. This nephritis has no tendency to disappear spontaneously since it depends upon severe lesions of the renal cells.

Causes and Treatment of Chronic Rheumatism.—Acute rheumatism is considered by many to be an infectious disease. There is no particular reason why it should be mentioned in the same breath with a very different disorder, chronic rheumatism. RALPH STOCKMAN (Brit. Med. Jour., Feb. 27, 1904) states that the term "rheumatic," while still not by any means satisfactorily defined, has gradually become much narrowed from the efforts of many observers to make more accurate diagnoses. Morbus coxæ, cóxa vara, Hogarth's nodosities, septic and gonorrheal arthritis are now happily recognized to be separate and distinct from each other and from chronic rheumatism. It is now generally held that chronic rheumatism implicates only the ligaments of the joints and more especially all the fibrous tissues of the muscles and bones. There is still an unfortunate indecision in the matter of its pathology. The essential pathological changes are confined to the white fibrous tissue. Hence the lesion affects the aponeuroses tendons, fibrous septa, sheaths of various structures and the fibrous parts of joints. Microscopically the lesion is seen to consist of a proliferation of fibrous tissue. The part is hyperemic but free from leucocyte engorgement. Frequently this thickening takes the form of a strand or cord running through the part. Sometimes the condition is either duplicated or else closely simulated by the lesion which arises after local injury from strains and sprains. To obtain perfect cure from the recurrent attacks, the fibrous indurations must be disposed of, and in all except the most recent cases, this is a decidedly difficult procedure. Massage and exercise, faradism and the injection of a solution of chromic acid, the latter being applicable only where the areas are sufficiently large, have been found to be most satisfactory. General massage is of no use. The knuckles and fists should be used for rubbing locally. As much as a year may be consumed in disposing of long-standing nodosities. Ten minims or less of a one-per-cent. solution of chromic acid in water may be injected. It may cause pain, but if suitably done, it will ultimately give great relief. There is often occasion to excise the nodes by the knife, and no hesitation should be felt in having recourse to this easy and sensible method.

After-history of Gastric Ulcer.—Seen from a medical or a surgical standpoint, the deductions from histories of these cases are of the utmost importance.

James W. Russell (Lancet, Jan. 30, 1904), who has had a large number of chronic out-patient ulcers under his care for a large number of years, states that as a result of purely medical treatment, his conclusions are as follows: Direct mortality 2.1 per cent., 4.3 per cent. have died from intercurrent disorders, 42.6 per cent. have recovered, 27.7 per cent. having had but a single attack, 14.9 per cent. having recovered after one or more relapses, 44.7 per cent. represented a group in which all the individuals were suffering from stomach symptoms of more or less severity, 14.9 per cent. had very positive attacks with intervals of immunity which apparently resulted directly from the treatment, 29.8 per cent., despite all that could be done, suffered almost continuously from pain. These cases appear to the author to represent those in whom surgical intervention is very clearly indicated.

SURGERY.

Obstruction and Distention as the Cause of Appendicitis.—As the result of experiments on dogs and from the study of cases in man, C. Van Zwalenburg (Jour. Am. Med. Ass'n, March 26, 1904) arrives at the following conclusions: Simple infection does not account for the suddenness of the attack nor early severity of the pathologic changes in acute appendicitis. The evident interference with the blood supply is best accounted for by an increased intra-appendicular pressure. Simply injecting bacteria into the appendix will not produce appendicitis unless used in abnormal amounts and of great virulence. Subperitoneal ligation of the appendix with a simple ligature without distention cannot be made sufficiently permanent to produce a general infection of the appendix, typical of appendicitis in the human being. Experiments in dogs show that hydraulic pressure equal to the arterial tension maintained within the lumen of the appendix for a short time is promptly followed by typical appendicitis. The blood supply in an extremity may be cut off with immunity for hours; but in the appendix the ever-present bacteria at once begin an infection, their entrance into the tissues being facilitated by the opening of normal and traumatic avenues by the very distention which cuts off the circulation. The importance of making a complete diagnosis and prognosis within the first twelve hours of the attack is emphasized. This study suggests the possibility of infections or other lesions being produced in other hollow viscera, especially in the gall-bladder, the stomach and intestines, by temporary overdistention.

Gonococcus Metastasis.—Suppurative lesions occurring in the course of a gonorrhea, other than those in the urethra, in which attempts have been made to demonstrate the gonococcus as the exciting cause, have been made by a number of writers, but the cases are comparatively infrequent. J. McColgan and J. M. Cooper (Jour. Am. Med. Ass'n, April 2, 1904) report an instance where, in a woman of forty years, a sudden attack of what was apparently rheumatism affected the thumb and index finger of one hand. The patient's husband had been under treatment for gonorrhea during the previous month, but no signs of infection could be demonstrated in the wife. No improvement took place and incisions made about a week later into the affected area resulted in the evacuation of a small amount of purulent material. The process extended to the hand and necessitated a freer exposure. The flexor tendon was involved and after healing had taken place, was considerably shortened. No joint anchylosis was present and the authors are inclined to believe that the condition was purely a tendovaginitis. Examination of the pus showed the characteristic organisms of Neisser. Attention is called to the necessity of routine examinations of the pus from such doubtful abscesses, especially those connected with the tendon sheaths. The liability to the transmission of the gonococci to others and the production of a gonorrheal ophthalmia is much more probable than where the disease is localized in the urethra, because in the latter case, definite precautions are usually insisted on. Whether the patient presents the symptoms or not, proper treatment directed to the urethral conditions should be employed in all cases.

Chloroform in Surgical Anesthesia.—A great deal of experimental work has recently been carried on in England bearing upon the administration of chloroform. Dudley W. Buxton (Med. Press, March 23, 1904) gives a further description of the Vernon Harcourt inhaler, which it will be remembered is so constructed as to give exact percentage vapors to the patient. In conclusion he says that the gist of his communication is that a vapor of chloroform not exceeding two per cent. is quite adequate for surgical anesthesia and that its use avoids most of the great dangers of that anesthetic. Such a percentage can be obtained with very great exactness by the use of Harcourt's inhaler. Its technic, which is exacting but not intricate, must be thoroughly mastered in order that the most satisfactory results can be obtained.

Surgical Treatment of Perigastric Adhesions.—It is a favorite belief here that American surgery has surpassed that of the Continent and of England. There is, however, still a good deal to learn from English students concerning the surgery of the stomach. Their journals are filled with the reports of successful cases which have received radical surgical treatment for so-called chronic dyspepsia. E. P. Paton (Lancet, Feb. 6, 1904) says some idea of the frequency with which adhesion about the stomach may be expected is shown by the following post-mortem records: In five per cent. of cases evidence of an active ulcer or of the scar of an old ulcer is present. Fenwick states that in 405 of such ulcers there are adhesions. The situation of these adhesions are as follows: In 143 cases they are between the stomach and the pancreas. In 92 cases to both the liver and the pancreas. In 31 cases the stomach is attached to the colon, liver, spleen and mesentery. Adhesions to the anterior wall are never met with. The history of cases suffering from perigastric adhesions is usually a long and unhappy one. They generally, if carefully traced, are referable back to an old acute attack giving the characteristic sign of ulcer. When these more acute symptoms have passed, the chronic disability shows little tendency to yield to treatment. Pain is not infrequently confined to one location. It is variable in its severity. It is not infrequently uninfluenced by the taking of food. It is frequently much influenced by posture. Exertions are in some cases very likely to bring on pain, sometimes with great suddenness and severity. Local tenderness is very frequent. It may be over the seat of the subjective pain, but not always so. Vomiting does not seem to be very frequent. In those cases in which the gall-bladder and stomach are involved, jaundice may occur. Careful dieting characteristically has no effect upon the pain, and a further point in diagnosis of the condition is that the general health as a rule does not suffer proportionately to the apparent extent of disease. In most cases a tentative diagnosis can be made which will be sufficiently strong to warrant exploratory incision. The treatment consists in the separation or division of the adhesions. This is easy, but the question of preventing their reformation is a very different problem. Exclusion of every element of sepsis is a very important factor. Absence of antiseptic solutions in the abdominal cavity is another. Peritoneal patches over all raw surfaces are of course very much to

be desired. Occasionally sterile oil silk has been used, but it is usually better not to insert foreign bodies into the abdominal cavity. Karl Vogel has shown that none of the membranes and other materials used to prevent peritoneal adhesions have any value, the best results having been obtained by the introduction of large quantities of sterile salt solutions. Promotion of free movement among the viscera by having the patient move from side to side in bed after abdominal section is far more important in the prevention of re-adhesion than any other procedure. The old method of keeping cases of abdominal section too rigidly at rest is probably responsible for many of these adhesions. Forty-two cases are recited in this paper, and the nature of the results are such as to make the most conservative reader agree that no case of chronic dyspepsia should be allowed longer to suffer on.

Surgery of the Prostate.—The immense amount of literature on this subject and the contentions of the espousers of the varied technics show that as yet no definite conclusion as to choice of methods has been reached. Thornley Stoker (Brit. Med. Jour., Jan. 30, 1904) deals with the removal of the prostate when the bladder has been opened, with the methods of opening the bladder and treatment of the parts subsequently. He is a champion of the suprapubic operation. When the bladder has been opened, the prostate should be thoroughly examined with the right hand, the left being in the rectum, which has previously been thoroughly cleaned. A pair of blunt end scissors are used to snip through the floors of the bladder and capsule of the gland. This incision should be made over the most projecting part of the larger of the two lobes. The whole gland may be deliverable through the one incision, but if the lobe first incised comes away without its fellow, a second incision should be made. It is well to carry the incision with the scissors well down into the tissue of the prostate. The question of attempting to preserve the prostatic urethra generally settles itself. The urethra may be so glued to the gland that it is torn away with it. Records show that cases do just as well when the urethra has been removed as those in which it has been preserved. As to the nature of prostatic enlargements, the author believes that there are three conditions of senile enlargement: (1) A true hypertrophy of the gland without interstitial growth. (2) The existence upon and within the substance of the prostate of one or more encapsulated tumors distinct from the substance of the gland proper, and either myomatous or adenomatous. (3) A mixed condition of true hypertrophy and interstitial growth of the second class. This condition is much the most common. Gilbert Barling, in the same issue, states that castration as advised by White, which was welcomed with such enthusiasm and vasectomy, which gave promise of equal brilliant results, have both fallen into disrepute in the treatment of prostatic enlargement. The unfortunate fact is, that the diseased enlarged prostate does not diminish as does the normal gland under section of these organs. He advocates Freyer's method of suprapubic prostatectomy. His conclusions are as follows: (1) It is possible to enucleate the prostate; (2) the prostatic urethra is almost invariably, if not always, removed with the organ; (3) if left it will necrose from want of blood supply; (4) stricture does not follow this damage to the urethra; (5) the operation often restores the function of the bladder to an absolutely normal condition. Cuthbert F. Wallace, in same issue, states that an anatomical knowledge of the normal prostate is most essential in these days. The term "fibrous capsule" is used to express the fibrous sheath derived from the rectovesical fascia. There is no capsule in the sense of a separable membrane such as invests the kidney. Nor can the prostate be shelled out of its surroundings like a lymphatic gland or the thyroid. He concludes (1) that the usual form of prostatic enlargement is adenomatous; (2) that this tissue may surround the urethra or form lateral masses or exist in all three parts; (3) that there is always left behind a definite lamented envelope containing glandular tissue derived from the expanded outer portion of the organ; (4) that the amount of envelope left on the surface of the tumor after removal depends on the depth at which the enucleating finger cleaves the envelope; (5) that the rectovesical fascia is not opened nor the plastic plexus of veins injured. (6) He suggests the term surgical capsule for the envelope formed from the prostate by the extension of the adenomata. It is a pathological formation. To its presence is due the small amount of bleeding and the absence of urinary extravasation. In the so-called total prostatectomy, the enucleating finger never passes outside the limits of the prostate, there being always some of this adventitious tissue left behind.

Etiology of Fibrous Orchitis.—Recently the opinion is gaining more and more ground that gonorrhea is an important cause of interstitial orchitis which formerly was looked upon as almost always syphilitic. F. Lesser (Münch. med. Woch., March 22, 1904) detected fibrous changes in 4.5 per cent. of all autopsies on males; in 70 per cent. of these there were other well-marked lesions of syphilis. In another, undoubted specific condition, lobulated liver, syphilis elsewhere was manifest in only 57 per cent., so that it is not wrong to assume that most of the other cases of orchitis were also syphilitic and that gonorrhea really plays a very subsidiary rôle and that the process generally remains restricted to the epididymis. Other unquestionable but rare causes are contusions, mumps, rheumatism, masturbation and bodily exertion.

Veratrum Viride in Surgery.—The physiological action of this drug has been more carefully studied by Dr. H. C. Wood than any other observer, says Chas. L. Bonifield (Am. Jour. of Obst., January, 1904). It relieves inflammatory pain and lowers the temperature. In appendicitis after the principles taught by Ochsner have been applied—that of keeping the stomach and bowels emptied to arrest the peristaltic movements—veratrum viride meets every other indication for treatment. It sustains the heart by making it work easier; it stimulates elimination of the poison by the liver, kidneys and skin; it lowers the temperature and relieves the pain. It is possible that by its action upon the circulatory system brings an army of leucocytes to the field of battle and in this way helps to destroy the invading army of germs. The circulation is much more profoundly influenced by veratrum than by hot and cold applications. In rapid acting hearts in postoperative peritonitis, after the bowels have been emptied, veratrum is a most valuable agent in slowing the heart's action. It is better than digitalis and strychnine, as it lessens the cardiac labor and gives time for rest between beats. Here, too, its eliminative action is most helpful. The preparation of the drug preferred by this author is Norwood's tincture. Where prompt action is wanted, as in eclampsia, it is best to give deep subcutaneous injections. Or, it may be given in this way in appendicitis, if it is desirable to keep the stomach empty. It produces some irritation at the point of injection, though the writer has never seen an abscess. The dose varies from five to thirty minims according to the size and age of the patient. The toxicity of the drug has been overrated by the rank and file of the profession. H. C. Wood says that it is one of the safest of all the cardiac depressants.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 30, 1904.

RENAL DECORTICATION VERSUS SECTION.

Guiteras has recently compiled the results of some 120 cases in which the diagnosis of chronic nephritis were reasonably well established prior to decapsulation. In each one of these patients, the postoperative changes, both from a clinical and pathological standpoint, were watched with extreme care. Looked upon in a light as favorable as might be compatible with accuracy, 16 per cent. of the total number may fairly be considered cured. Forty per cent. were believed to be improved, 11 per cent. were unimproved and in 33 per cent. the operation was followed by early death. Suker reports the histories of 15 patients with albuminuric retinitis, for whom the kidneys were decapsulated. Of these, all save one had died within the two-year limit, and the history of the remaining case was vague.

Walker Hall and G. Herxheimer in the *British Medical Journal,* April 9, 1904, consider that the value of these statistics is minimized by the following considerations:

"First the operation has been necessarily restricted to the latest stages of the disease and has often been performed only as a last hope. Second, the exact stages and extent of chronic nephritis do not permit of accurate diagnosis. Third, chronic nephritis is as a rule characterized by acute exacerbations and frequent remissions. Its anatomical course is in the main a progressive one and the remittent stages often occur under treatment other than that of decapsulation. Of the above 33 per cent. mortality, 26 per cent. died from chronic interstitial nephritis and of the remainder in 25 per cent. death occurred from the so-called chronic parenchymatous nephritis and in 75 per cent. diffuse nephritis was assigned as the cause."

Emerson, Johnson, Claude, Albarran and Bernard are practically unanimous in their belief, which in every case is based upon experimental work, that no new blood vessels of a sufficient size to affect the nutrition of the kidney to any appreciable degree are formed. Enough work has been done on this subject to justify the conclusion that the belief which was originally held both by Edebohls and by others who were early interested in the operation of decapsulation, viz., that the improvement, which often follows its employment, was due to an increased vascularization of the part, is erroneous.

Clinicians, who have observed very marked improvement follow decapsulation in a small but certain number of cases, have been at a loss to understand the cause of the change. It has been claimed rather widely that experimental work on the healthy organ was of no value, first, because the pathological changes, to combat which the operation might be indicated in the human being, were absent in the animal; and second, because of the morphological differences existing between the human kidney and those of the lower vertebrates. The latter objection has not in general been viewed as having much material significance, and an answer to the former is at length at hand.

After creating an artificial nephritis in the kidneys of some fifty-five rabbits, Hall and Herxheimer found practically the same conditions to obtain as was reported in the case of the normal kidneys decapsulated by previous investigators.

Neutral ammonium chromate, the substance originally employed by Burmeister, proved to be the most certain and satisfactory way of inducing the experimental nephritis. From .5 to .75 c.c. of a 2.5 per cent. solution was injected into rabbits weighing from 1,500 to 2,000 grams. This invariably produced an intense acute congestion, followed by degenerative necrosis of the epithelium of the convoluted tubules; by the appearance of quantities of hyaline casts and a variable amount of albumin. Glomerular and interstitial

changes were conspicuously absent both immediately after the injection and for some time thereafter. In the case of those animals who survived twenty days, however, small cell infiltrations were visible around the medium sized blood vessels, indicating that a possible interstitial change was beginning. The effects of the irritant varied in different animals, although an effort was made to obtain a relation between the body weight and the amount of chromate injected. In most cases in which albumin appeared in the proportion of four to one thousand, death subvened in convulsions or in coma within ten days. Concerning hyaline casts in the human urine, it is interesting to note that these were invariably present.

From the anatomical standpoint, decapsulation does not, in the opinion of these authors, offer any advantages. If, as they say, "there exists no anatomical basis for the operation";—increased blood supply to the part—"in acute degenerative nephritis, it is surely impossible that in chronic nephritis the capsular changes will be less marked." This is based on what seems a reasonable belief that the laceration and hemorrhage into the parts would, in the presence of a tendency to sclerotic change, increase the formation of scar tissue.

Have we not at length reached a standpoint from which a different view must be taken of the causes which underlie the unquestionable improvements which do occasionally take place in patients operated upon by this decapsulation method?

For about two years, clinicians and experimental workers have been at variance with each other, the one set of observers claiming that a few cases were unquestionably improved, while the others held that in view of laboratory findings, this improvement was chiefly in the imagination of the operator. The reply of the surgeon to these insinuations was briefly to the effect that in the eyes of the laboratory man, "all cats have nephritis."

Pel, Jaboulay and others have for some time been suggesting that the improvement, evidence of which has been tabulated by Guiteras, arises more from the reaction of the operation upon the sympathetic ganglia, rather than in the increased blood supply to the part. Simple section may therefore give as good results as complicated decortication. This is a new phase of the situation which has much of theoretical and practical interest in it.

THE LAW AND THE CRIMINAL.

The recent conviction for murder, in this city, of an undoubted victim of sadism, has probably been a source of surprise to not a few medical men particularly to those interested in medico-legal cases. This instance serves to point out a marked deficiency in that important guardian of society, the criminal law. Only too frequently do its dignified interpreters ignore, consciously or unconsciously, the manifold susceptibility of the human mind to loss of equilibrium. To be sure, the opinion of the alienist, as expert testimony, in cases of suspected mental derangement, is given the proper degree of consideration. But the impalpable forms of insanity underlying many offenses against the social order, are rarely recognized by counsel or judge. It is in the imperfect defense and unjust conviction of such cases, that a severe indictment must be brought against the legal fraternity.

It is almost thirty years since Lombroso in his book, "L'Uomo delinquente," gave birth to the modern science of criminology. His views, however, have not yet received universal acceptance. Students of criminality are still arrayed in two opposing camps, the one maintaining that the criminal is born, not made, the other, that he is the product of his environment. From the viewpoint of the biologist it matters little which of these views is the correct one. In each he perceives a moiety of the truth. For is not the animal organism a plastic entity acting upon his surroundings, in turn to be reacted upon by them? It bears the imprint of the past and yields to the molding influences of the present. Heredity has long since been accorded its proper rank among the motive forces of humanity and yet the law will hardly recognize it. To show that the culprit had criminal or degenerate antecedents, is not accepted as a defense. Unless tending to corroborate other direct evidence as to mental disability, such evidence would not be allowed to go to the jury.

"What," it may be asked, "is the cause of this failure of jurisprudence to recognize the biological basis of crime?" In the first place, the modern legal system places an exaggerated value upon the authority of the past and the edifice of the law is largely built upon the practices and precedents of our forefathers. The researches of psychologist and criminologist are given scant courtesy by the learned disciples of Blackstone. In the second place, the education of the legislator and the lawyer is but ill adapted to prepare

a proper soil for the reception of modern scientific thought.

In his "Riddle of the Universe," Ernest Haeckel stigmatizes the august guardians of the law as having "but a superficial acquaintance with that chief and peculiar object of their activity, the human organism, and its most important function, the mind." All that is required of those whose duty it is to shield society from its enemies is a knowledge of human nature and the criminal code. But this is not sufficient. A poor pedagogue indeed would he be whose lore extended little beyond the subject-matter of his instruction and the rules of his school. It is now recognized that the successful instructor must have a thorough grounding in psychology and its parent, physiology. Moreover, in the large cities there is a growing demand for teachers whose knowledge extends into the domain of neuropathology, who have the ability to recognize and deal with defective children and abnormal types. How much more important it is that he who is called upon to judge his fellow-man, should not only possess the trained observation of the psychologist, but should also be familiar with the various clinical forms of mental disease and the extensive literature of criminology. This would be too much to expect of the ordinary lawyer or jurist, for the knowledge required of them in their own technical sphere is sufficiently deep and comprehensive. But is it too much to demand that he who specializes in criminal law and particularly, he who presides over a criminal court, shall have taken his degree in medicine preparatory or subsequent to the prosecution of his legal studies? This would be expecting of the jurist that breadth of perspective and liberality of mind which are indispensable in this enlightened age.

In the Republic of Plato, the rulers of the State are philosophers. Is it altogether Utopian to expect that our modern legislators should possess that illuminating wisdom, which, poised upon the broad basis of a liberal culture, transcends time and place, and scorning the petty considerations of personal gain or ambition, labors for the weal of humanity? Only then will the statutes be framed with a just consideration for the mental and moral delinquents. The spectacle of the State leading to the chamber of execution a trio of brothers in whom the curse of Cain was the culmination of a career of moral deterioration, will no longer offend the eyes of civilization. Let it be demanded, at least, that they who promulgate the laws and they who hold the scales of justice, shall be learned men, scientists, if you will, in touch with the divine harmony of the universe, and not mere "bachelors of law."

NERVE SURGERY FOR THE RELIEF OF PALSIES.

Nerve anastomosis is an important recent development in the surgery of the peripheral nerves for the relief of palsy. Since the work of Faure and Foret in France, and Ballance and Steward in England (1895) a few cases have been from time to time reported. The work, however, received its most decided stimulus in Kennedy's report of a successful case of facio-spinal accessory anastomosis for convulsive tic which was followed by experiments on dogs that cleared up some points in the physiology of restoration of function. Kennedy divided peripheral motor nerves supplying extensor and flexor groups of muscles and sutured the proximal stump of the nerve supplying the extensor group to the distal stump of the nerve supplying the flexor group. A temporary disturbance of motion was soon followed by complete restoration of function. Furthermore the brain centers representing these groups of muscles were found reversed on electrical irritation of the cortex. Through a process of education the cortical centers which represented the extensor and flexor groups of muscles had become reversed. A fact which is still without a comprehensive explanation. While the application of facts derived from experiments on the lower animals cannot always be applied to the human subject without reserve, nevertheless this work of Kennedy's has received important corroboration in the operations recently undertaken for the relief of old facial palsies from mastoiditis or from interstitial neuritis as in Bell's palsy. It has been found that if the distal stump of the facial nerve be engrafted in the proximal stump of a healthy nerve there is more or less shorter restoration of function in the facial distribution. After a longer or shorter period of reeducation the restoration of function is very considerable, which in some instances has been almost complete.

The nerves chosen for anastomosis with the facial were first the spinal accessory, and more recently the hypoglossal. The latter has been chosen by the more recent operators in this country. Frazier, of Philadelphia, reports one case, and Taylor and Clark, of New York, three cases. In all of these cases the report followed too soon after the operation to know the extent of recovery. The consequent paralysis following

division of the hypoglossal and the suture of the proximal stump to the distal stump of the facial contributes one of the chief objections to the operation. This is partially overcome by a side implantation of the facial with only partial division of the hypoglossal, and other similar modifications, but in these instances the results of the operation cannot be expected to be as good as the results following the complete anastomosis. Ballance and Stewart have proven experimentally that to get a more or less complete restoration of function after nerve suture there must be a nice apposition of the sutured ends. Another more or less serious drawback to faciohypoglossal anastomosis is the difficulty of the operation as compared with the faciospinal accessory anastomosis. The latter operation being comparatively simple. We must know the exact results of many operations before we can say which procedure is preferable.

ECHOES AND NEWS.

NEW YORK.

Dr. R. W. Taylor.—Dr. Taylor has removed from his old offices where he has been so many years to 142 West Forty-eighth Street.

The New Bellevue.—Plans for the new Bellevue were exhibited last Saturday at Columbia University, and they promise much for the alleviation of the wretched condition in which New York City now finds herself for adequate hospital accommodation. The buildings may cost the city $10,000,000 before they are finished but no better appropriation could be made to the conservation of the working power of New York City's poor. New York is the largest and most important city of the United States. Its city hospital accommodations are painfully inadequate. The new hospital, if built on the plans submitted, will be not only of great service to the city but will be an ornament as well. Some of the details of the plans will be presented to readers of the Medical News in a subsequent issue.

Hospital Appointments.—The following gentlemen of the College of Physicians and Surgeons secured hospitals during the past week: Rochester City, J. C. O'Connor. St. John's (Yonkers), William Blancard. St. John's (Brooklyn), 1st, R. L. Moorhead. Orange (N. J.) Memorial, Julius Levy. St. Francis, 1st, R. H. Dieffenbach, C. D. Cleghorn, S. W. Wynne, W. H. Whiton. Lincoln, 1st, C. C. Kimball, B. G. Allen, C. W. Woodson. St. Mary's (Brooklyn), 1st, M. T. McSheehy, E. J. Murphy, W. E. McCollum, M.D., 1903. St. Barnabas (Newark, N. J.), G. H. Schenck; Alternate, F. H. Wilson. New York Skin and Cancer, Fred Wise. Almshouse and Workhouse, J. C. Hance, C. H. Weir.

Report of St. Mark's Hospital.—Owing to the great suffering among the poor during the severe winter, St. Mark's Hospital has been taxed to its utmost to give relief to the sick, not only in its wards, but also in its out-patient department. The annual report of the board of managers shows, however, that the hospital has responded as never before in its history to all these demands. During the year ending in March, 4,594 hospital days of treatment were devoted to patients without compensation, while eighty-six days were given to patients who could pay less than a dollar a day. In the out-door department, 2,031 patients made 13,217 visits to the hospital, while 1,660 meals were given to poor persons. In all, 3,344 patients were treated, of whom only 77 died, and 26 of these within three days after admittance to the hospital. During the year, in spite of the additional demands upon the resources of the hospital, the board of managers has paid off one mortgage of $5,000, and reduced another by $2,500. Taking into account all expenditures, the average cost of each patient a day was $1.81.

Church Collection for Hospitals.—Hospitals which receive money from church collections, find their appropriations curtailed this year, because at the last collection the contributions fell off from $83,000 to $75,000. The committee in charge of the fund met in the Mayor's office recently and apportioned it as follows: Montefiore Home and Hospital, $6,400; Mount Sinai Hospital, $4,453; Roosevelt Hospital, $4,216.99; St. Luke's Hospital, $3,758.34; St. Mary's Free Hospital for Children, $3,757.97; German Hospital, $3,159.05; Hospital for the Ruptured and Crippled, $3,154.20; Post-graduate Hospital, $3,133.27; Nursery and Child's Hospital, $3,094.41; Mothers' Home of Misericordia, $2,867.15; Lincoln Hospital and Home, $2,717.70; Infants' Asylum, $1,841.73; Home for Incurables, $1,741.10; Isabella Heimath, $1,754.29; Sloane Maternity Hospital, $1,639.53; French Hospital, $1,530.29; Beth Israel Hospital, $1,417.22; Orthopedic Dispensary and Hospital, $1,401.60; Hospital for the Lying-in Society, $1,399.81; Homeopathic (Flower) Hospital, $1,099.90; St. Mark's Hospital, $960.67; New York Ophthalmic Hospital, $920.66; New York Infirmary for Women and Children, $794.03; New York Eye and Ear Infirmary, $694.16; Babies' Hospital, $667.85; New York Polyclinic Hospital, $663.56; Skin and Cancer Hospital, $653.57; Manhattan Eye and Ear Hospital, $650.52; J. Hood Wright Memorial Hospital, $606.64; Hahnemann Hospital, $526.27; House of the Holy Comforter, $472.26; General Memorial Hospital, $464.33; Lebanon Hospital, $387.81; College and Hospital for Women, $250; Ophthalmic and Aural Institute, $250; St. Andrew's Convalescent Hospital, $250; Convalescent Home, $250. The amount distributed is $64,000, and is known as the "undesignated" fund.

PHILADELPHIA.

Bequests to Charity.—By the will of George Huster, property to the value of $25,000 is bequeathed to various hospitals and homes in this city.

Pasteurized Milk Society.—This institution, which began its work eight months ago by distributing 4,500 bottles of milk monthly, is now giving out 3,000 bottles daily. Six branch stations are now in service and another will probably soon be started in Kensington. The price charged for the milk barely covers the cost of Pasteurization. Contributions since the plant started aggregate $5,500.

Pathological Society.—The annual conversational meeting of the society was held on Thursday evening, April 28. The address was delivered by Dr. M. J. Rosenau, Director of the Hygienic Laboratory of the Marine Hospital Service, the topic selected being "Some Studies in Yellow Fever." Following the address a reception was tendered Dr. Rosenau at the University Club.

Friend's Asylum, Frankford.—The report of this institution for the past year shows that 116 patients

were admitted, 48 of these being men. The total number treated was 265. Several patients were refused admission because of lack of room. A new wing is to be erected at a cost of $20,000; this will furnish thirteen rooms for patients and two sun parlors. Of the 1,738 male patients that have been treated at the institution the largest number of any one class were farmers, 289; of clerks there were 165; merchants, 145; physicians, 46; lawyers, 33. The causes of insanity in the 2,271 patients were, in part, ill health, 420; mental strain, 406; intemperance, 246; domestic trouble, 134; love affairs, 107 women and 28 men.

State Charity Exhibit.—Nearly 1,000 photographs, charts, etc., of the hospitals, asylums, homes, and prisons of Pennsylvania have been shipped to St. Louis for exhibit at the Fair. Among them will be illustrations of the hospitals at the bottom of mine shafts and the Pennsylvania Railroad service with which every engine east of Pittsburg is being equipped. Among the statistics of Pennsylvania for 1904 are: Invested in charitable institutions, $60,000,000; the State is caring for 16,000 people in homes, 30,000 in alsmhouses, and 12,000 in insane asylums. The annual charity expense is $14,000,000.

To Prosecute Unlicensed Physicians.—Recent disclosures by the coroner's office regarding the baby farm traffic in this city have led to concerted efforts to put a stop to this and other illegal medical practice. The County Medical Society has set aside a fund for this purpose and will appoint a committee of three to aid the Coroner, District Attorney and the Director of Public Safety in obtaining evidence against and prosecuting illegal practitioners. It is said that the latter number at least 100 in the city. The *Press* is endeavoring to put in shape a bill that will be introduced at the coming session of the legislature to more closely restrict or make impossible the doings that have been recently unearthed at many of the "farms." To draft the bill there has been formed a committee consisting of Dr. E. E. Montgomery, Dr. J. C. Clark, Dr. Cadwallader, of the Woman's Medical College, G. W. Pepper, representing the Bar, and Miss Richmond, of the Society for Organizing Charity.

CHICAGO.

To Receive Ten Thousand Dollars on Account of Amputation of Frozen Feet and Hands.—It is said that Ellen Robinson, a graduate of the Illinois Training School for Nurses, Class of 1902, now at the Presbyterian Hospital in this city, recovering from the amputation of her hands and feet, will receive from the Alumni of the school a fund of $10,000, to be applied to her support the rest of her life. Miss Robinson, while nursing at Monticello, Ill., this winter, lost her way in a blinding snowstorm, and her hands and feet were so badly frozen that amputation was necessary.

Bazaar to Aid Hospital.—After nine years of work, the people of South Chicago are preparing to establish in the center of that district a permanent home for the South Chicago Hospital of sufficient capacity to meet the demands of that part of the city. With that object in view, the directors of the only institution of that kind located in South Chicago district announce a two weeks' bazaar for the purpose of starting a permanent hospital fund. It is intended to replace the present small and inadequate institution with a hospital building involving the expenditure of $100,000.

Osteomalacia.—Dr. Thomas A. Davis read a paper on this subject before the March meeting of the Chicago Surgical Society, and reported a case. The author believes that this is the first case that has been demonstrated in North America in a male, with apparent arrest of the disease, reported one and one-half years after operation. The patient was a Norwegian, aged thirty-three years. The family history, previous history, present illness, exploration of fracture, pathological fracture, diagnosis, differential diagnosis, etc., were gone into extensively by the essayist, also the treatment, subsequent history, and skiagrams of the case were exhibited. Retrospectively, taking the symptomatology as completely evolved in this case, the author said the simplicity of diagnosis was quite apparent. With but a slight knowledge of the disease, the inference could scarcely be incorrect. But taken at such a time as that previous to operation, the diagnosis was not so easy. These were the objective symptoms: Shortening of stature, curvature of the spine, barrel-shaped chest, none of which had been noticed by the patient. The subjective symptoms were rheumatoid pains in the extremities and spine, with possible mental manifestations of stupidity, and a mild degree of melancholia and myasthenia. As to the objective symptoms, one commonly meets with them among laboring people, without attempting to determine the cause as to rickets or occupation, etc. There was nothing characteristic about the pains complained of, and it is yet questionable as to the mental disturbance. It is quite clear that there is no individual pathognomonic symptom of osteomalacia, and still authors have expressed astonishment at the late date of recognition, or complete failure to diagnose the disease. At the present time, with no knowledge of the cause of the disease, its real nature cannot be recognized until advanced bone changes have taken place. In reviewing the history of a large number of cases, the author finds that the symptoms almost universally mentioned are rheumatoid pains in the extremities and spine, without swelling, accompanied by myasthenia, these symptoms preceding for some months deformity and fracture. With the history of such symptoms, the X-ray should show the lessened density of the bones, and serve to establish a diagnosis. Dr. D. J. Davis presented an extensive pathological report of this case. He gave a brief résumé of the theories advanced to explain osteomalacia, none of which he said is satisfactory. It is quite likely that softening of bones is produced in a variety of ways, and that different forms probably require entirely different explanations.

Extirpation of Suppurating Kidney.—Dr. Frederic A. Besley read a paper on this subject before the same society, and presented a case. Ether was the anesthetic used, and the organ was removed through a lumbar incision. The patient made a perfect recovery. He said a retrospective view of the case presented one important question, namely, Was the removal of the kidney the wisest procedure, or would it have been better surgery to have made an effort to restore the patency of the ureter and preserve the organ? In this particular case he did not think he was justified in jeopardizing the patient's life by exposing him to a prolonged operation and a prolonged convalescence.

GENERAL.

A Dispensary for Paterson, N. J.—That the city of Paterson is to have a dispensary of its own was decided April 21, at a meeting of the Charities and Correction Committee of the Board of Aldermen. The clerk of the board was instructed to solicit bids for drugs on a schedule submitted by City Physi-

cian Van Noort which would supply sufficient to run the dispensary for about three months. Dr. Van Noort said that he had received the dispensary outfit belonging to the late Dr. Myers, the gift of his brother, George A. Myers, and that it would require few additions. A prescription clerk will be engaged by the city for about three hours a day at a salary of about $25 a month, and it is expected that the new plan will result in a reduction of expenses.

Addition to Harvard Medical School's Infirmary.—The work of constructing the contagious ward of the Stillman Infirmary at Harvard is to begin soon, and it is hoped to have it completed by next fall. The recent gift of $25,000 from Mr. Stillman, added to his previous gift of $50,000, has made it possible to carry out the project in a manner completely satisfactory to the college authorities. The new building is to be of the same style architecturally as the infirmary, and is to be connected with it by a semicircular passageway of two stories, the lower of masonry and the upper an open colonnade. In dimensions the new building will nearly equal the present building, being about 80x40 feet, and four stories high.

The Tri-State Medical Society of Iowa, Illinois and Missouri.—This society will meet in St. Louis, June 15, 16 and 17. An interesting program is being prepared, and some of the most distinguished physicians and surgeons of the country will attend the meeting. The president is Dr. W. B. La Force, Ottumwa, Iowa; and Dr. Louis E. Schmidt, 1003 Schiller Building, Chicago, is the secretary. Dr. James Moores Ball, 3509 Franklin Avenue, St. Louis, is Chairman of the Committee of Arrangements.

American Climatological Association.—The Committee on Nomenclature of this association suggests the following classification for cases of pulmonary tuberculosis: *Incipient.*—Slight physical and subjective signs, with history indicative of pulmonary tuberculosis. Sputa, if present without bacilli; *First Stage.*—Definite physical signs of localized infiltration; total involvement less than half a lobe, whether at one or more points; cough and expectoration with bacilli; constitutional symptoms, slight. (In disseminated cases expectoration and bacilli may be absent with constitutional symptoms more severe.) *Second Stage.*—Infiltration of single or multiple areas approaching or equal in amount to one lobe; or smaller area in stage of softening; cough and expectoration with bacilli; constitutional symptoms, severe. *Third Stage.*—Infiltration in excess of one lobe or if less in stage of well developed excavation; more severe constitutional symptoms. They also suggest a classification of results of treatment as follows: *Progressive.*—All essential symptoms and signs continue unabated. *Quiescent.*—Constitutional symptoms slight or entirely absent; physical signs improved or unchanged; cough and expectoration with bacilli still present. *Arrested.*—Absence of all constitutional symptoms; expectoration and bacilli still present; physical signs may or may not persist; foregoing to have existed for at least three months. *Apparently Cured.*—All constitutional symptoms and expectoration with bacilli absent for a period of three months. *Cured.*—All constitutional symptoms and expectoration with bacilli absent for a period of two years under ordinary conditions of life.

American Climatological Association.—The twenty-first annual meeting of the Association will be held in the banquet room of the Aldine Hotel, Chestnut Street, above Nineteenth, Philadelphia, on June 2, 3, and 4, 1904. The following program has been arranged: President's Address, by Dr. J. C. Wilson, Philadelphia; Climatology as a Study in Medical Schools, by Dr. S. E. Solly, Colorado Springs; The Climate of Santa Barbara, California, by Dr. W. H. Flint, Santa Barbara; The Climatology of Muskoka, Ontario, Canada, by Dr. J. H. Elliott, Gravenhurst, Ont.; Weather Observations in the Adirondack Mountains, by Dr. Lawrason Brown, Saranac Lake, N. Y.; Some Meteorological Comparisons of the Winter of 1903-4, by Dr. Carroll E. Edson, Denver, Col.; The Climates and Diseases of Central America and Panama, by Dr. J. Edward Stubbert, New York City; Ocean Bathing, by Dr. Philip Marvel, Atlantic City, N. J.; A Study of the Delirium Accompanying Heart Disease, by Dr. R. G. Curtin, Philadelphia; Phases of Arterial Sclerosis or Painful Cardiac Affection, by Dr. Judson Daland, Philadelphia; The Mechanical Treatment of Organic Heart Disease, by Dr. Charles E. Quimby, New York; Effect of Altitude upon Blood Pressure, by Drs. C. F. Gardiner and Henry W. Hoagland, Colorado Springs; A Study of Infection in Pulmonary Tuberculosis, by Dr. F. M. Pottenger, Los Angeles; What Shall We Do with Our Tuberculous Patients? by Dr. F. I. Knight, Boston; Some Cases of Pus Infection Simulating Pulmonary Tuberculosis, by Dr. Robert H. Babcock, Chicago; Pulmonary Tuberculosis in Children, by Dr. William Duffield, Phœnix, Arizona; Tuberculosis in Children, by Dr. Thomas Darlington, New York City; The Use of the Fluoroscope as an Aid in the Physical Diagnosis of Pulmonary Tuberculosis; its Limitations and Its Advantages, Based on Three Years' Experience, by Dr. Charles L. Minor, Asheville; Recent American Contributions to the Methods of Prevention and Treatment of Pulmonary Tuberculosis: (1) Antituberculosis Societies and Their Work, (2) Exposition in Baltimore, (3) Facilities for Out-door Treatment, (4) New Sanatoria, by Dr. A. C. Klebs, Chicago; A Plea for the Revision of Terms Used in Physical Examination of the Lungs, by Dr. J. Hilgard Tyndale, Lincoln, Neb.; The Pitch of the Normal Pulmonary Valve Sound, and the Practical Significance of Its Changes in Acute Lobar Pneumonia and in Emphysema of the Lungs, by Dr. Howard S. Anders, Philadelphia; Meteorologic Conditions in the Causation of Lobar Pneumonia, by Dr. James M. Anders, Philadelphia; Some Unsettled and Important Problems in the Treatment of Acute Lobar Pneumonia, by Dr. Beverley Robinson, New York City.

Association of American Physicians.—The nineteenth annual meeting will be held in the New Willard Hotel, Washington, D. C., May 10 and 11, 1904. The following program is announced: The President's Address, by Wm. T. Councilman, Boston; General Business; The Influence of Supra-Renal Extract upon Absorption and Elimination, with Demonstrations, by S. J. Meltzer and John Auer, New York; Polyuria in Typhoid Fever, by M. H. Fussel, H. S. Carmany and H. Hudson, Phila.; Polyuria in Typhoid Fever, by James C. Wilson, Philadelphia; Cases of Venous Thrombosis Occurring in the Course of Typhoid Fever, by W. S. Thayer, Baltimore; Clinical Studies in Arteriosclerosis, by Alfred Stengel, Philadelphia; An Investigation of the Effects of Cardiac Stimulants, Especially Strychnine, on the Blood Pressure in Febrile Conditions, by R. C. Cabot, Boston; A Supposed Cause of High Tension Pulse in Nephritis, by W. H. Thomson, New York; Poisoning by Illuminating Gas—A Clinical Study of Fifty Cases, by W. G. Thompson, New York; Nephrectomy for Renal Tuberculosis, by I. N. Danforth, Ann Arbor; Abdominal Pain from Unsuspected Irritation of the Internal Inguinal Ring,

by Chas. G. Stockton, Buffalo; The Mechanism of Exophthalmos, by W. G. MacCallum and W. B. Cornell, Baltimore; Diabetes Insipidus, by Thos. B. Futcher, Baltimore; A Case of Prolonged Male Hysteria with Autopsy, by S. Weir Mitchell and Wm. G. Spiller, Philadelphia; Some Unusual Forms of Acute Myelitis, by B. Sachs, New York; Infectious Neuritis with Report of Cases, by Jas. J. Putnam, Boston; The Clinical Features, Prognosis, and Treatment of Cerebrospinal Meningitis in Infants and Children, by Henry Koplik, New York; A Case of Spasmodic Stricture of the Esophagus with Sacculation, Treated by Dilatation, and Later, by Gastrotomy, by James Tyson, Edward Martin and Thos. Evans, Philadelphia; Idiopathic Dilatation of the Esophagus—Cardiospasm, by B. W. Sippy, Chicago; Annual Dinner at the Willard Hotel; A Lantern Slide Demonstration of the Protozoon-like Bodies Found in Scarlet Fever, by F. A. Mallory, Boston; A Lantern Slide Demonstration of Trypanosomes, by Chas. S. Bond, Richmond, Ind.; Election of Members; The Relation of Cells with Eosinophile Granulation to Bacterial Infection, by E. L. Opie, Baltimore; A New Case of Chloroma with Leucemia, with a Study of the Cases Reported since 1893, by Geo. Dock and A. S. Warthin, Ann Arbor; The Neoplasm Theory of Leukemia, with Report of a Case Supporting This View, by A. S. Warthin, Ann Arbor; Types of Splenic Anemia or Splenomegaly, by Alfred Stengel, Philadelphia; On the Cultivation of *Trypanosoma Evansi*, by F. G. Novy, W. J. McNeal and C. B. Hare, Ann Arbor; The Agglutination and Filtration of Trypanosomes, by F. G. Novy and W. J. McNeal, Ann Arbor; Zonal Necrosis of the Liver, by E. L. Opie, Baltimore; Attempts to Produce Liver Necrosis by Venous Injections of Intracellular Bacterial Toxins, by R. M. Pearce and C. K. Winne, Jr., Albany; Exhibition of Specimens of a Malignant Adenoma of the Liver, by Geo. L. Peabody, New York; Rhythmic Lateral Displacement of the Heart as a Sign of Unilateral Pleuritic Exudate, by Chas. L. Greene, St. Paul; Pneumopericardium, with Report of a Case, by W. B. James, New York; Three Cases of Probable Psittacosis, by H. F. Vickery, Boston; Addison's Disease with and without Adrenal Tuberculosis, by C. F. Withington, Boston; Report of a Case of Acromegaly, by Chas. L. Greene, St. Paul; A Study of the Tubercle Bacilli Isolated from Three Cases of Tuberculosis of the Mesenteric Lymph Nodes, by Theobald Smith, Boston; Studies on the Etiology of Variola with Demonstration of Microscopic Preparations, by Wm. T. Howard, Jr., and Roger C. Perkins, Cleveland; Chronic Thrombosis of the Pulmonary Arteries in a Case of Multiple Serosities, Simulating Aneurism of the Thoracic Aorta, by E. F. Cushing, Cleveland; Pneumococcic Arthritis, by S. Solis Cohen, Philadelphia; Pulmonary Actinomycosis, with Report of a Case, by S. Solis Cohen, Philadelphia; Election of Officers and Concluding Business.

"Tonnage" in the Medical Profession.—An editorial in the May *Scribner's* takes for its theme the ideal of an executive in a large metal-refining concern, viz., "tonnage" and its writer applies the statement to the professions, especially that of medicine. He goes on to say, "It is the opinion of one of the oldest medical instructors in our country that the schools of to-day aim to turn out more graduates and better students of medicine than ever before, and that they succeed, but do not turn out as good doctors, on the average, as they did forty years ago." The reporter does not know when or by whom this assertion is made, hence he can have no idea as to the weight of authority back of it. Granting the right of free thought and open expression of opinion, and realizing how much the question of medical education has occupied the attention of those most fitted to speak during the past year or two, one can concede that the above-mentioned "instructor" may be right. At the same time, however, one may assume that he is wrong and base the defense of his propositions upon the results that are being achieved by the more recent graduates. Of course, more graduates and better students do not make up the large percentage of good doctors; for the rightful application of that term recognizes the varied and almost indescribable qualities which such must possess. It is certainly a good thing to have at one's finger tips the theory of medicine, but it is also quite another thing to put those theories into practice; in other words, to be resourceful. Perhaps the apparent difference between the men of to-day and of forty years ago who have gone out to practice medicine is due to the tendency everywhere so manifest to migrate from the country into the city. Forty years since there were fewer and smalled cities and comparatively few doctors ever thought of settling down in a town numbering over five thousand inhabitants. Country doctors are essentially self-reliant, and perhaps that is what was meant by the term "good doctor." There must be all sorts and conditions of men in medicine as elsewhere and it is quite natural that the college-bred and thoroughly equipped young doctor should choose for himself a field in which he might reap the cost of his education as soon as possible, leaving for his less trained though perhaps thoroughly efficient classmate the sparsely settled districts. Speaking of the physician of to-day, the article says: "What he bemoans to-day is the intense prevailing desire for organization. He says that the schools are becoming teaching shops and the instructors teaching machines. The large number of students forces the subdivision and specializing of instruction, and each specialist seeks naturally to magnify his office. The student is passed successively or simultaneously through a certain number of courses which are more and more 'thorough,' but often leave him with an inadequate knowledge of the general facts and principles of his profession. In science as in the social order 'time makes ancient good uncouth.' The proportion of 'good doctors' in the multitude issuing from the modern schools is probably as great as the old schools turned out; the positive number of the less competent is necessarily larger. But the least fitted of these will not do the harm in some ways that the best-trained often, in good faith and ignorance, were wont to do. The 'tonnage' of the profession seems portentiously large, but the one principle that we may be confident works now as surely as it ever did, is the survival of the fittest." Perhaps the "tonnage" is larger than necessary. There are equally good arguments for and against this view, but it seems to the writer that one need scarcely worry about an overproduction of physicians; for in our profession as in every other the law of supply and demand is constant and either factor will adjust itself to keep as nearly perfect a balance as is possible if one can only afford to be patient.

OBITUARY.

Dr. Lorenzo J. Kohnstamm, of New York, forty-four years old, died on Monday last.

Dr. Wilbur F. Nutten, one of the best known medical practitioners of Western New York, is dead at his home in Newark, N. Y., from heart disease,

at the age of sixty-four years. He was a graduate of the College of Physicians and Surgeons of New York.

Dr. Edward Henry Lee, of Chicago, was almost instantly killed last Sunday morning. Dr. Lee was educated in Heidelberg and Vienna. He was also a student at Bonn University and later studied medicine at Würzburg University. He was a surgeon at the Alexian Brother, West Side and Cook County hospitals.

CORRESPONDENCE.

OUR BERLIN LETTER.

Berlin, April 1.

ARRIVAL OF ANGLO-AMERICANS FROM VIENNA—RELATIVE MERITS OF BERLIN AND VIENNA POST-GRADUATE WORK—PROF. ORTH'S ANSWER TO VON BEHRING ON THE QUESTION OF TUBERCULOSIS—THE ANGLO-AMERICAN CLUB—SUCCESSFUL INOCULATION OF SYPHILIS ON ANIMALS OTHER THAN HUMAN BEINGS—PROGRESSIVE METHODS OF THE GERMANS AS REGARDS HOSPITAL CONSTRUCTION.

Owing to the Easter holidays and the coming medical congress in Leipzig the present month will be very quiet, medically speaking. The University is entirely closed, and not only are the large and more important of the University clinics and courses not given, but even the majority of the minor courses, so that it is rather difficult to obtain the work one desires. During the past week there have been a large number of arrivals of Anglo-Americans from Vienna, where the same condition of affairs is present, and which evidently prompted the present pilgrimage to Berlin. Unfortunately, however, they are finding themselves disappointed and many are already wishing themselves back.

With this commingling of students from the great centers of medical learning there has naturally been considerable discussion of the oft mooted question as to the relative merits of Berlin and Vienna as regards post-graduate work. It has always been a matter of the keenest moment to Americans, and is unquestionably the first decision that confronts him when he thinks of studying abroad. There are a large number of Americans in Berlin at present who have been to both places and who are therefore competent to judge, and I have tried to obtain some sort of general consensus of views upon this subject. Like most questions of this nature it seems to be an entirely relative matter. You will find some men condemning the work in some particular branch, while others regard it in the highest esteem, and altogether the opinions are so diverse and varied that it is hard to form them into a good general classification. It seems to be not only a question of the particular line of work sought for, but also, and to a large extent, on the individual temperament and the student's previous training. There are many who will be very well satisfied with a particular course, but which will be regarded as highly unsatisfactory by a more advanced student; and on the other hand there will be a large difference of opinion by two men of equal capabilities otherwise, which depend upon nothing but obscure and subtle differences in individual taste. Judging from the standpoint of choice of subject, however, the consensus of opinion seems to be that in pathology, skin, and diseases of the stomach, and nervous system the opportunities in Berlin are far better than those in Vienna, whereas, on the other hand, Berlin is no match for Vienna in internal medicine, where the keener and more profound methods of the Vienna School come into play. In surgery, bacteriology, children's, ear, laryngological and genito-urinary diseases, the two cities are about equal. These distinctions, however, should not in any way be understood to be hard and fast, because, for instance you can undoubtedly get excellent courses in pathology in Vienna, and on the other hand, some of the internal medical work in Berlin will prove very satisfactory. They only intend to express a general average, and if one intends to get the most of his time in the course of his work in Europe, it will pay him best by going to both places and absorb the best essences from both.

Virchow has not been dead quite two years and although it cannot be said that he is sadly missed, nevertheless you hear every once in a while expressions of fond remembrance which the present régime will probably not recall. Nobody denies that his successor, Orth, is a very competent man and probably the best pathologist in Europe; nevertheless the difference between the personalities of "The Founder of Modern Pathology" and his successor is striking. Virchow was a genial old soul and bore himself with a quiet dignity that is in strong contrast to the gruff, abrupt and distant nature of Orth. There was an intimacy between master and pupil in Virchow's time that makes the deadly fear in which the assistants regard their chief at the present time quite amusing. It is evident that he is ruling things with an iron hand and gives very little opportunity for the play of any sentiment. Even the medical fraternity of Berlin have a wholesome fear of the pathologist, for they regard him as a deadly antagonist in debate. It is conceded by all that he is one of the best masters of medical polemics that Berlin has seen, and his answer to von Behring some weeks ago at the "Gesellschaft" on the question of tuberculosis, is still being spoken of as one of the masterpieces of medical debate. Backed by his enormous knowledge and his keen critical insight, combined with a clear diction and forceful delivery, he is an unmerciful antagonist and woe to him who meets his ire. Curiously enough, the only man in Berlin who has the happy distinction of being in any way a rival of Orth is a "horse-doctor," the pathologist of the veterinary school, a man of most profound learning and an excellent debater.

The Anglo-American Club is still in existence, and what is more, prospering far beyond the expectations of its founders. The general plan of the meetings has been changed from those heretofore, and instead of hearing papers written by the members, there is an invited guest at each meeting, some distinguished medical man from Berlin, who holds a "Vortrag" on some topic of general interest. It was found that interest in the society slackened under the original scheme, whereas at present the weekly meetings are looked forward to. It is not difficult, as was originally thought, to get the highest "talent" to come, and nobody who has been invited has yet refused the invitation. Thus far some of the most distinguished personages in Berlin have been present, among whom may be mentioned, Ewald, Olshausen, Grawitz, Israel, Wasserman, Peck, etc. We have been very fortunate also in having the opportunity to hear two of our best known Americans as well: Prof. Scripture, of Yale, and Prof. Simon Flexner, Director of the Rockefeller Institute. Prof. Scripture gave a most interesting and fascinating demonstration and lecture on "Experimental Phonetics." The night of his lecture was made into a kind of gala occasion, and the club invited many distinguished laymen, among whom may be mentioned the Consul-General of Berlin, Mr. Mason, and some professors from the Academic and medical university. Prof. Flexner, who incidentally is working in Prof. Salkowski's laboratory, lectured on the "Etiology and Treatment of Dysentery" and gave an excellent résumé of the im-

portant work done by himself and his coworkers on this subject. He was elected subsequently as the first honorary member of the Anglo-American Medical Club of Berlin. At the last meeting the surgeon Israel spoke on the "Surgical Treatment of Nephritis." The best part of the lecture dealt with an analysis of Edebohls' work and his statistics. He tried to show that even according to Edebohls' own published records the latter had failed to cure one case of chronic Bright's Disease, and he claims that the reported cures are simply those where the nephritis was combined with a movable kidney. He also reported six cases of his own with one death and no cures.

Up to the present the inoculation of syphilis on animals other than human beings has been entirely futile. It may be of interest to know that this has finally been accomplished by Lassar, who announced some weeks ago at the Berliner medicinische Gesellschaft the successful inoculation of a chimpanzee. After the regular period of incubation, typical lesions presented themselves, which were confirmed by microscopical examination. Since then he has successfully inoculated another chimpanzee, and the dead specimen was presented at the society two weeks ago. It showed typical macules and papules and other undoubted specific lesions all over the body and especially on the soles and feet.

The progressive methods of the Germans as regards hospital construction is again exemplified in the new Charlottenburg Krankenhaus which is rapidly nearing completion and which will be opened very shortly. Prof. Grawitz conducted a party of American students through the different buildings a number of weeks ago. It is built on the most elevated part of Charlottenburg, affording a delightful view of the surrounding country. It is constructed on the pavilion system, the separate buildings being connected by corridors and naturally with the aid of the most modern methods of hospital construction. The whole covers an extensive plot of ground and will have a capacity of about 800 beds.

THE CORONER'S BILL.

To the Editor of the Medical News.

Dear Sir: The so-called Coroner's Bill has passed the legislature and is now before the Mayor of Greater New York for his signature. If the physicians of Greater New York would write a personal letter to the Mayor in favor of Senator Elsberg's Coroner's Bill it would greatly help the Committee on Legislation to place this important bill upon the statute books of this State.

This bill had its origin in the New York County Medical Association, which has agitated the subject independently and in association with other medical bodies in Greater New York for many years, and finally a joint committee, representing the counties of New York and Kings, of which Prof. Stephen Smith, M.D., was chairman, and with the aid of Mr. James Taylor Lewis, Counselor of the New York State Medical Association prepared the draft of a bill which with some modification is the bill introduced in the legislature by Senator Elsberg. The Committee examined the system of verifying deaths in Massachusetts and many other States and foreign countries and concluded to recommend that the office of Coroner with its jury in Greater New York be abolished and the duties connected therewith be transferred to already existing departments of the city government, namely, judicial duties to the city magistrates, the medical duties to the Department of Health, the civil duties to the City Chamberlain and the legal duties to the District Attorney.

The office of Coroner in the City of New York is the butt of the paragrapher, the subject of ridicule by the press and is little respected by the community at large and the reason therefor seems to me to be in the fact that the Coroner exercises with his jury extraordinary authority and fills many offices so that there is no man to be found to-day with such power of mind and versatility of talent who can as Coroner sit upon the bench as a judge, deciding the kind of evidence which shall be submitted to his jury, who leaves the bench to go to any place to take the ante-mortem statement of some poor injured mortal, and, in case of death, to decide its cause, incorporating in his decision the latest researches in chemistry, biology and pathology and yet only one of the eleven Coroners of the City of New York is a lawyer.

The Coroner adds another terror to sudden death in the City of New York, for if he suspects suicide then Section 775 of the Code of Criminal Procedure commands that his jury must be present while the inspection of the body is being made. The Coroner is higher than the sheriff and replevins merchandise from him in civil suits. The Coroner's system in the City of New York is a relic of bygone ages and has outlived its usefulness. In analyzing the so-called Coroner's Bill we can understand how the several existing departments of the city government can do with a great saving of the city's money the work of the Coroner's office much more satisfactorily than it has been done heretofore. The bill transfers the judicial functions of the office of Coroner to the present city magistrates, whose duties are not mixed but essentially those of judges, and the legal duties attending the inquest will be conducted by the District Attorney, in a magistrate's court, and will have the character and dignity which befits proceedings always of a solemn import to parties immediately concerned and often of far-reaching influence upon the welfare of the community in which the suspected crime was committed. The civil duties, such as replevining merchandise from the sheriff, are transferred by the proposed bill to the City Chamberlain, an officer of the city government who is in every way qualified for the responsibility imposed upon him. The medical duties are transferred to a bureau to be created in the Department of Health, with medical examiners who will act under a chief who shall be a skilled and practical pathologist and who shall have practised his profession in this State for five years and at least three of which shall have been spent in laboratory work in pathology and bacteriology. The Department of Health will assume all of the duties connected with investigating the cause of death, bringing to its aid well-equipped chemical and biological laboratories, conducted by expert scientists. The researches in these laboratories have received honorable mention in the great medical congresses of the world and the practical results have stimulated other cities to copy its admirable work. And it now remains for the Mayor and the Governor to give the City of New York the much-needed relief from its inadequate Coroner's system.

Yours very truly,

E. Eliot Harris,
Chairman, Committee on Legislation.

An Improvement on the Air-cushion in Surgery.—It is so important to get a good view of the field of work that any method which serves to aid in bringing the posterior portion of the retro-abdominal wall nearer to the surface is of value. Here we use, especially for operations on the kidney, various forms of cushions. G. Kelling (Zntrlbl. f. Chir., Jan. 30, 1904) illustrates an admirable addition to the ordinary operating table. It consists simply of a cross-bar which passes beneath the midtrunk region.

SPECIAL ARTICLE.

PHYSICAL CHEMISTRY VERSUS BIOLOGY IN THE DOCTRINES OF IMMUNITY.*

BY PROFESSOR PAUL EHRLICH, M.D., LL.D.,
OF FRANKFORT-A.-M., GERMANY.

Prof. Ehrlich devoted himself mainly in this lecture to a discussion, polemical in character, of the physicochemical investigations of Arrhenius and Madsen, the Danish physicists. They applied the methods of physical chemistry to the study of toxins and antitoxins and one of their beliefs is, that tetanolysin is a uniform substance possessing only a weak affinity to its antitoxin and that its neutralization occurs in accordance with the law of Guldberg and Waage. His own doctrine of the pleurality of toxic constituents was discussed in connection with the assertions of these observers and then he alluded to the fact that their views only met with a favorable reception in certain scientific circles which lacked special competence in serotherapeutical questions. Ehrlich protested against the attempts of these authors to claim exclusive priority in the development of these questions, for the method of partial neutralization of toxins followed by them was opened and developed by himself. Equally unwarranted is the reproach that his (Ehrlich's) investigations are inaccurate and have been conducted without sufficient regard for possible sources of error. His most important results have been confirmed by A. and M., especially as regards the existence of toxoids and their occurrence with varying degrees of avidity. Neither will he admit that he has used the simplest possible explanations although he always began with the simplest, and as in the case of diphtheria toxin, substituted more complex ones only when the experimental results made this necessary. The contention, moreover, that his investigations represent merely an application of Thomson's principles in his studies of affinities between strong acids and bases is incorrect, because the latter worked with material substances only.

Ehrlich next took up the points of departure between his methods and those of other investigators. In the first place it was to be determined whether in the production of toxoids a change in avidity for antitoxin occurred. The only available method for this was that of partial saturation or neutralization, which was defined in detail. If the toxin were a single substance of uniform composition and the antitoxin possessed for it a strong affinity, like that between hydrochloric acid and potassium, the quantities of toxin which disappear or are neutralized in these mixtures, would be in direct ratio to the quantity of added antitoxin. In fact the process of neutralization takes place in a different manner which was illustrated by a series of diagrams, in which the experimental results were presented in graphic form. The first, designated by Ehrlich as the spectral mode of representation, shows step by step the extent of diminution in the number of toxic doses effected by a definite small quantity of antitoxin. Another method, the "linear," employed by Arrhenius, is mathematical in character, and in it the quantities of antitoxin added are represented on the abscissa and those of the active toxic doses present on the ordinates. Ehrlich does not consider that this method has any advantage over the former and is objectionable because the graphic line corresponds only in its middle part with the values actually found, and toward the beginning and ends shows considerable deviation.

The interpretation of the phenomena of neutralization was next considered and it was shown that three different zones can be distinguished in the spectral mode of representation. In the first zone one combining unit of antitoxin removes on the average either one-half or one entire lethal dose. As there is reason to assume that in the case of an ideal, absolutely pure toxin one combining unit removes exactly one lethal dose, the foregoing result indicates that in this zone pure toxoid, or pure toxin, or a mixture of equal parts of toxin and toxoid, designated by Ehrlich as hemitoxin, is neutralized. The existence of hemitoxin is possible only in case the toxoid has precisely the same avidity as the toxin, and from this it follows that, as assumed from the beginning and moreover confirmed by Arrhenius, in the transformation of toxin into toxoid, no change in avidity occurs. Pure toxoid occurs often in the form of a prototoxoid, which possesses a stronger avidity for antitoxin than all other components of the toxin and thus manifests its presence that to the solution of toxin containing it a certain quantity of antitoxin can be added without lessening in the slightest degree the toxicity. The existence of prototoxoids is denied by Arrhenius, but the criticism is not applicable because the substance has been repeatedly tested and prototoxoids have also been positively demonstrated in the case of other poisons and analogous substances, ferments and agglutinins.

The second zone in the spectrum is of relatively short extent and is characterized by the fact that one combining unit removes only a fraction of the lethal dose. This is the zone of decisive significance for the hypothesis advanced by Arrhenius. The third zone is called by Ehrlich the toxone zone. The toxone is one of the primary products of secretion of the diphtheria bacillus, possessing the same haptophore group as the toxin, but of far less avidity, and entering in the process of partial neutralization therefore last into combination with antitoxin. Its toxophore group differs from that of toxin, being incapable of producing acute effects, such as cutaneous necrosis and death. Toxone is responsible for the diphtheritic paralysis occurring in guinea-pigs between fourteen and thirty days.

An extended discussion then followed in which Ehrlich attempted to refute the objections advanced by the physicochemical school against his theories. Arrhenius concluded from his experiments in neutralization of ammonia by boric acid, that inasmuch as the neutralization of tetanus-toxin proceeds in the same way it is superfluous to assume the existence of different components and sufficient to assume a single uniform toxin with weak affinity for its antitoxin. In reply Ehrlich stated that at the outset of his investigations he was led to assume a strong affinity between toxin and antitoxin. This opinion was supported by the experiments of Dönitz and Heymann, who demonstrated the extraordinary rapidity with which diphtheria toxin introduced into the circulation combines with the toxophile receptors in the tissues. It must therefore possess a high degree of avidity. The protective and curative properties of the serum indicate that the antitoxins possess at least as strong an avidity as the tissue receptors. Furthermore the therapeutic experiments of Dönitz in animals and of Madsen on red cells prove that the antitoxin when once bound, becomes so firmly fixed that the specific serum fails after a time to produce any curative effect. This indicates that after fixation of the toxin, secondary chemical modifications transform the primary labile combination into a stable one. Ehrlich was finally able to show that toxin and antitoxin unite with great avidity, and that certain variations which occur with different specimens of toxins could be referred to the presence of toxone.

The evidence which Arrhenius advanced to account for the assumption that toxin and antitoxin are actually

* Second Herter Lecture, delivered at Johns Hopkins University, Medical Department, April 13, 1904.

substances of weak avidity, was then discussed. He commented on the fact that biological data which speak against this view are either entirely ignored or set aside under arbitrary assumptions of an inexact investigation. The sole support advanced is the tetanus curve. The entire calculations of these authors proceed from the assumption that neutralization of toxin and antitoxin is an interchangeable or reversible reaction. If it can be shown that the process is not a reversible one, then the basis is withdrawn from all the reckonings and deductions of Arrhenius. No experiments have been made on this point by Arrhenius himself, but v. Dungern has taken up the subject by applying the procedure used by Danysz for other purposes, of successive additions of toxin to antitoxin. The conclusions to be derived from these experiments are that the union of diphtheria toxin and antitoxin does not proceed in accordance with the ammonia and boric acid scheme. The observed phenomena of combination are explicable only upon the assumption of a complex constitution of the diphtheria poison. The facts find their best explanation in the action of a toxone and an epitoxonoid, and the immunizing action of apparently neutralized toxins can thereby be explained. Constituents of the diphtheria with weak affinity after combining with antitoxin may eventually become so firmly bound that this union can only be incompletely broken by toxin of stronger avidity.

Prof. Ehrlich then referred to the experiments of a similar nature made by Dr. Sachs at his suggestion, with tetanolysin. For the latter which is the basis of the investigations of Arrhenius, it was found that similar statements could be applied and therefore that the premises underlying his entire calculations and constructions of graphic curves are inapplicable. The linear representations of the calculated values of toxins as demanded by Arrhenius for all cases, must be rejected whenever the phenomena above noted are present. Allusion was then made to the fact that from the purely physicochemical point of view, the conceptions of the authors presented numerous vulnerable points which would soon be exposed by competent authority. A few opposing arguments of a biological nature were then considered, beginning with tetanus. Tetanolysin on account of its property of decomposing quickly and the difficulty of conducting hemolytic experiments with absolute accuracy, is ill adapted for precise determinations of the kind under consideration. As the lecturer graphically described it, neutralization experiments with this substance encounter on the one side the Scylla of incomplete union and on the other the Charybdis of destruction of the poison. It does not seem comprehensible that the calculations should be based on the assumption that the toxin consists of molecules of poison with uniform composition. On the contrary it is highly probable that specific toxoids are present, which must enter into the calculations as well as the toxins. The amount of toxoid was unknown and is at present indeterminable. To escape from this dilemma, Arrhenius assumes that the production of toxoid results from an equable weakening of all the toxic molecules. Thus the toxic solution would not be a mixture of dissimilar components. This assumption must be rejected on general grounds and is disproven by the demonstration of prototoxoids, as well as by the investigations of Tarobi on ricintoxoids. A number of other objections were also discussed and to meet these, Ehrlich claimed that Arrhenius had scarcely anything of a positive character to offer, except his tetanolysin table, which corresponds fully with the theoretical calculation. It should be emphasized, however, that this favorable result was secured only once in comparison with a large number of failures. What adds to the skepticism is the fact that both of Madsen's diphtheria curves, which were published in refutation of Ehrlich's conceptions, have since been shown to be erroneous. At present there are no satisfactorily demonstrated facts which warrant the application of Arrhenius' conceptions to the diphtheria toxin. The large variations of the dissociation-constants, as determined by the calculation, necessitate the assumption of an extraordinary multiplicity of poisons, whereas Ehrlich's conceptions are satisfied with the conception of a much smaller number.

In concluding this lecture he claimed that his views furnished a far better explanation than those of Arrhenius of numerous facts in the domain of toxins. These include the process of spontaneous enfeeblement of toxins, their passage into a state of stability, the reduction of the toxone zone, and the capacity of completely neutralized poisons to produce antitoxin by means of epitoxonoids. He ended with the conviction that what he had established through long years of work concerning the nature of the diphtheria poison would in the course of time prove itself real and vital.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held Saturday, February 27, 1904.

The President, Augustus S. Knight, M.D., in the Chair.

Complete Removal of the Penis.—Dr. Spooner presented a patient from whom the entire penis had been removed because of cancerous disease some three weeks before the meeting. The specimen of cancer was also presented. Notwithstanding the removal of the organ, the patient is able to hold his water perfectly. In answer to a question, Dr. Spooner replied that the muscles involved in holding the urine are the circular fibers at the opening of the urethra and that these are not interfered with by the operation. They constitute the so-called internal sphincter of the bladder and are composed of involuntary muscle fibers. Some voluntary muscle fibers, however, are found along the urethra in the perineal portion, and these of course remain untouched. Hence enuresis does not follow. This compresser urethra muscle is a portion of the levator muscle and effects the purpose of an ailing patient to hold his urine very well, yet gives him control over the evacuation of his bladder a few times.

Rupture of the Intestines.—Dr. Flint presented a case in which, as the result of a blow on the abdomen, severe rupture of the upper part of the small intestine near the beginning of the ileum had occurred. Notwithstanding the usually hopeless outlook of these cases, the patient was operated upon successfully. Within three hours after the accident had happened the ruptured places were sutured, the abdomen thoroughly flushed out and the patient recovered without any serious complication or delay.

In discussing Dr. Flint's case Dr. Putnam said that he had recently operated upon a fireman who had suffered from rupture of the ileum almost at the same part evidently as that in which Dr. Flint's patient had been injured. In this case the result was fatal. At first the patient refused operation, and when, after forty-eight hours, the operation was permitted, he was already in the throes of death from peritonitis and died from shock. In this case the intestines seemed to have been filled with air and to have ruptured somewhat like a paper bag, when by the force of the blow they were driven against the spinal column.

Obscure Stricture of Esophagus.—Dr. F. N. Wilson reported a case in which for several days a child

vomited every particle of food that was given it. This food was vomited in such a way that it had evidently never reached the stomach and a stricture of the esophagus was found to be present. The interesting feature of the case was the absence of history pointing to any possible etiology of the stricture. The child had suffered from scarlet fever some months before and this had evidently been of very severe character, since the little one had been in bed for six weeks. The little one had become so much run down for lack of food that when an operation for the dilatation of the stricture was attempted it died before proper dilatation could be accomplished. The stricture was about 8 cm. from the teeth and there was absolutely no history of irritant materials having been swallowed or any trauma that might have occasioned the stricture which was found to exist after death. There was very little fibrous material associated with it, as could be seen from the specimen which was exhibited. Dr. Frank Daniels said that the stricture was evidently connected with the attack of scarlet fever, since only under very special complications were children in bed for so long as six weeks with this disease. It is difficult, however, to say just what the process which brought it about would be, though as secondary infections are quite common with scarlet fever, the possibility of such a complication with scarlet fever is easy to understand.

Sarcoma Treated by Toxins.—Dr. William B. Coley presented a patient who had suffered some three years ago from a round-celled sarcoma of the dorsal spine. At the time he came under observation he was about twenty years of age. The tumor was of enormous size involving several of the lower dorsal and some of the upper lumbar vertebræ. The patient had lost about fifty pounds in weight. During the growth of the tumor so much pressure had been exerted upon the spinal cord that not only was the patient confined to his bed, but there was total paralysis of the lower extremities as well as of the bladder and rectum. Just before he came under observation the patient was so weak that he was unable to turn over in bed. The diagnosis of sarcoma had been made by Dr. Virgil P. Gibney who called on Dr. Coley to administer the toxins at the Montefiore Home just two years ago. Before the administration of the toxins a small portion of the tumor was removed and the diagnosis of round-celled sarcoma made from the very typical clinical history of the case, which was confirmed by Dr. Harlow Brooks, a pathologist at Bellevue Hospital.

Details of Treatment.—About four drops of the mixed toxins of the bacillus of erysipelas and *Bacillus prodigiosus* were given daily. A temperature of 103 to 104° F. developed after each injection. Almost at once the patient began to show improvement, especially in his general condition, and the local signs, by lessening of the size of the tumor, also improved. Six months after the injections were begun he was able to be around on crutches. In November he was shown before the New York Surgical Society and had regained nearly all the weight that he had lost besides recovering almost completely the use of his limbs, so that he was able to walk very well with the aid of a cane. Last February, one year after treatment had begun, he was able to walk perfectly without support of any kind and his general health had improved to such a degree that he was able to resume his former occupation. Dr. Coley considers this to be one of the most remarkable results ever obtained from the use of the toxines. Of the diagnosis in the case there can be no doubt, since specimens from the tumor were examined by thoroughly competent pathologists and some of these specimens are still to be seen by those who might have any possible doubt about the nature of the affection.

Other Favorable Results.—Dr. Theodore Dunham said that the patient presented by Dr. Coley was the most remarkable one that he had seen with the exception of a patient under the care of Dr. Ahlbe some time ago which seemed absolutely hopeless. The growth was an enormous tumor on the side of the head. The toxins when administered produced a decided reaction and the growth of the tumor, which had been very rapid before, stopped at once. Before long the tumor began to reduce in size and then practically disappeared. Dr. Dunham has seen the child several times since, and the cure seems to be enduring.

Dr. Dowd said that while the toxins did not succeed in all cases, he had seen some remarkable results that had been thus obtained and he considered that further observations along this line should be made, especially in the severest cases, in order to obtain further data as to the value of this method of treatment.

Relief of Paralysis.—Dr. Frank Daniels said almost more surprising than the cure of the tumor itself was the complete restoration to the patient of the use of his limbs and his urinary and rectal functions after five months of pressure paralysis with involvement of both bladder and rectum. Usually it is considered that in this length of time some degeneration will have taken place in the nervous fibers of the cord, and the present excellent condition of the patient is therefore a subject for congratulation and the source of the greatest encouragement as regards the possibilities of these cases to get well.

Inhibitory Action of Toxins.—Dr. Coley said that in very many cases of sarcoma the mixed toxins of erysipelas and of the *Bacillus prodigiosus* produce a distinct inhibitory action upon the further cellular growth of the neoplasm. In some cases, however, this inhibitory action is not quite equal to the new growth of the tumor, and consequently the toxins fail to give relief. When the malignant neoplasm is extremely active the toxins therefore may prove unavailing. In most cases, however, the toxins inhibit the growth of the tumor for a time at least. In not a few cases this inhibitory action is so marked that the tumor begins to grow less in size at once and as the general condition of the patient is dependent apparently upon toxins absorbed from the neoplastic cells, this soon begins to improve. There can be no doubt now, in the mind of any one who has followed cases of sarcomata treated by the toxins, that they are wonderfully curative under favorable conditions. Dr. Coley has now had twenty-four cases which have been well from two to ten years. Sixteen of these cases have been well from five to ten years. One died of local recurrence at the end of eight years. One of local recurrence after two and a half years, and one of abdominal metastases after having remained well for over three years.

Treatment of Cicatricial Esophageal Stricture.—Dr. Theodore Dunham said that he suggested some years ago, in a paper read before the Harvard Society, certain methods of securing the passage of a thread through an esophageal stricture for the purpose of having instruments, guides and the like find their way through tightly closed strictures of the esophageal wall. As is well understood, it is important to reduce the danger always present in operations for dilatation of the esophagus by the passage of a guide from either side, that is, whether the stricture is to be dilated from above downward, or from the stomach upward. It is not always possible, however, to pass even a flexible guide through the tortuous strictures that exist in the

esophagus. If, however, fluid can find its way through the stricture, Dr. Dunham has shown that a thread may readily be washed through even the smallest strictures and then as gastrostomy is done, the thread may be used to draw a larger piece of cord or a piece of rubber tubing that may aid in the dilatation of the stricture, or may be useful in many ways in facilitating further operative procedures looking to the relief of the patient by making the stricture passable.

Thread Through Nostril.—In cases in which the patient is for instance a young child and the tongue prevents the passage of the thread, or where in adults a certain nervousness causes the tongue to interfere with its passage, the thread may be washed through the nostril. This Dr. Dunham tried first on himself and found that it was not accompanied by any serious discomfort and he now uses it, confident of success, where sometimes before much time was wasted in getting the thread through the mouth. The most important element in having the thread flow properly through the tube, is to have it as far as possible, perfectly straight. No slack must be allowed, and the flow of the thread must be checked every few moments in order to prevent any snarling. Others who have tried to wash threads through narrow strictures have been of the opinion that if some small heavier object were placed at the end of the thread it would be carried along more readily by the stream of water. This is not true. The more flimsy the thread the better does it flow in narrowing tubes, and the better is it kept in the center of the stream where movement is most rapid and there is least likelihood of its movement being interfered with.

Cord as Dilator.—Once a small string has been passed through a tight stricture, it may be hooked out of the stomach through the gastrostomy opening with a bent probe. A larger cord may then be drawn down, and, adopting the suggestion of Dr. Agbey, this cord may be used by means of a saw motion to affect an enlargement of the path through the stricture. Cutting with the cord thus, seems to be reasonably safe. The mouth and the gastrostomy opening have to be protected while the sewing is done by means of bent, grooved, metallic instruments in order to avoid the occurrence of unnecessary lesions. Besides the cord, an olive pointed instrument may be drawn through the stricture thus further dilating it. Dr. Dunham has had a series of olives made in order to secure gradual dilatation. At times Dr. Dunham has found that the drawing of a piece of tubing, which is put on the stretch, through the stricture, and then allowed to become thicker by its elasticity after it is in place, will affect a very gradual dilatation of the stricture, though not infrequently it will be found that this does not remain in place, but is gradually worked out by movements of the tissues.

Illustrative Cases.—Dr. Dunham reported a series of illustrative cases, two of them operated upon by himself, and some seven others reported to him by other surgeons who have found his methods very useful in securing the dilatation of esophageal strictures. In the first case in which he found the washing of a thread into the stomach the only possible means of securing dilatation of the stricture, he failed on three separate occasions to find the cardiac orifice of the esophagus to go through a gastrostomy wound in spite of the most careful search. In this case from neglect the dilated stricture became closed up once more and the patient refused to drink the water necessary to secure the passage of the thread into the stomach. It was then that Dr. Dunham, after having first tried it through his own nose, succeeded in washing the thread into the stomach by means of the tube passed along the floor of the nostril. Dr. Dunham has found that while at first it seemed more advisable to do the operation without an anesthetic, anesthesia is preferable, for the manipulations are very painful and the operator is apt to be discouraged by the complaints of the patient from accomplishing such an amount of dilatation as will really prove effective in lessening the symptoms present in the case.

Points in Technic.—Dr. George Brewer said that no operation is more trying to the surgeon than dilatation of a tight esophageal stricture. One of the most serious difficulties with regard to the passage of sounds through a stricture is that where there has been a decided narrowing of the esophageal lumen for a considerable period there is almost sure to be a diverticulum of the esophagus formed just above it. If sounds are passed then they will almost inevitably find their way into this diverticulum and the use of any force to pass sounds will surely lead to fatal results by perforation of the diverticulum with infection of the thoracic tissues. Hence the necessity so often for dilatation from below. Where the stricture is very tight, however, and close to the cardiac orifice, it is often a difficult matter to secure the entrance of instruments. Dr. Dunham's method of passing a thread then, is extremely helpful and saves a very difficult and almost impossible situation. Instead of using grooved pieces of metal to protect the soft parts, when a cord is employed with a sawing motion to enlarge the stricture, Dr. Brewer has found that a large, long spatula makes a better guard for the mouth, at least. It must not be forgotten that several strictures may exist in the esophagus and Dr. Brewer on one occasion had the olive-pointed tip of an instrument catch on the shoulder of a stricture through which it had passed and remain below the strictures some 15 cm. from the teeth imprisoned between two strictures. It was hard to know what would be necessary in order to secure its removal. A thoracotomy from behind was thought of, or the possibility of securing it by operating from the cardiac end of the stomach. Dr. Brewer succeeded, however, in making a cup-shaped snare which caught the olive and carried it with it in its course between the strictures.

Element of Spasm.—Dr. Dowd said that the element of spasm in esophageal strictures must never be forgotten. It not infrequently happens that when the specimens are obtained from a case of serious stricture of the esophagus, they are found not to contain much fibrous tissue, nor to have been especially thick and tight. It is evident in these cases that the irritability of the muscles near the point of stricture easily set up spasm and that this shuts up the narrowed lumen of the esophagus completely, though there was actually not a stoppage effected by the stricture itself. Hence the story so often seen on hospital sheets with regard to patients suffering from stricture of the esophagus not being capable of permitting the passage of a sound on the first day, and yet allowing it to pass easily afterward.

Technical Details.—Dr. Putnam said that the passage of the thread required attention to details. A little water was better than much. The thread has to be kept well on the stretch and the operator must remember that just when he is sure that the thread is down a gush of water may bring it out once more.

Dr. Brewer said that in one patient in whom he had attempted to pass the thread, the patient did not care to try to swallow it in the usual way with water, but taking a mass of thread he chewed and swallowed it, and actually succeeded in getting portions of it into the stomach.

Treatment of Spasm of the Esophagus.—Dr. Egbert Grandin said that for the treatment of a spasm of the intestines atropine or hydrobromate of hyoscine were

very effective. In the cases after operation within the abdomen when paresis of the gut occurs, these remedies, if given to their physiological effects, often give good results. It would seem worth while then to employ them as tests of the existence of spasm in these cases so as to be sure that there is real pathological condition as well as the spasm present.

NORTHWESTERN BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Regular Monthly Meeting, held March 10, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

A GENITO-URINARY SYMPOSIUM.

The Local Treatment of Gonorrheic Infections.—Dr. H. R. Loux read this paper. He stated that, although a continuous service of eleven years in one of the largest genito-urinary clinics in America had afforded him unusual opportunities for observation, he had never written a paper upon the treatment of gonorrhea, because no method heretofore suggested proved, upon prolonged trial, to be an advance worthy of commendation. Clinical observation in thousands of cases convinced him that gonorrhea is too often grossly mistreated. He deprecated the use of strong, irritating injections because they aggravate the disease and damage the urethra, and stated that treatment of acute anterior urethritis by irrigation is to be condemned because it causes an extension of the disease by continuity; he quoted statistics, reasons and authoritative statements to show that these opinions represented the beliefs of the leading and most conservative genito-urinary surgeons. The speaker stated that during the past year and a half the results at his clinic at the Jefferson Hospital and in private practice, had been much better than ever before; this statement he based upon the observation of several thousand cases of gonorrhea at all stages. The reasons for this improvement he ascribed to careful local treatment in which he abandoned, absolutely, the use of any drug as an injection which can cause the slighest irritation. Dr. Loux stated that, in a general way, his methods of treatment were as follows: For acute gonorrhea, he prescribed light diet, with very little meat, no fats, fruit or alcoholic beverages, but allows as much skimmed milk as the patient can drink. If the infection is confined to the anterior urethra, he prescribed the injection of two drams of a ten per cent. solution of argyrol, held in the urethra ten minutes; this injection is made in the morning, at noon and at night. Internally, he prescribes capsules of copaiba, cubebs and sandalwood three times daily. This treatment is practised for one week, during which time the discharge will almost if not entirely cease, there will be no pain or irritation by the injection or upon urination, and the gonococci will disappear. If, at the end of one week, the urine remains continuously shreddy, a weak solution of astringents is employed and of these drugs he preferred zinc sulphate, iodide, chloride, hydrastin or berberine muriate, but emphasized that these astringents should not be used during the first week of the disease and never in solutions sufficiently strong to produce pain or irritation. If the two glass test shows cloudy first and second portions of the urine, showing the presence of anteroposterior urethritis, he irrigates the anterior urethra with a warm solution of boracic acid in order to remove the accumulated secretions. Then he makes deep instillations of twenty per cent. argyrol solutions once daily or on alternate days; the inflammation of the anterior urethra is treated in the manner already described. The writer quoted from statistics of 400 cases treated since July, 1902, by the methods described and stated the advantages as follows: simplicity; the relief afforded the patient from pain and irritation; the extreme rarity of complications; shortened duration of diseases, in that an average time required for cure in acute cases was twenty-one days, whereas by the older methods practised at the clinic and in private work, the best average obtainable was forty-two days.

Dr. Loux then discussed the treatment of gonorrhea in the female, the methods of which are best described by an illustrative case: A. G., aged twenty-one years, came under observation June 5, with acute vaginitis, endometritis and urethritis for which she had been under treatment in New York for one week. Typical symptoms of gonorrhea were present; microscopical examination positive. The vagina was dilated to full extent by means of speculum. To every portion of the vaginal mucous membrane a 50 per cent. argyrol solution was applied, and the same to the urethra by means of a cotton-tipped probe. The interior of the uterus was then freed of accumulated secretions by means of a cotton-wrapped applicator, after which the 50 per cent. argyrol solution was applied to the cervix and the body of the uterus. These applications are repeated two or three times, so as to fill the uterine cavity with the solution. This local treatment was carried out every second or third day. After eight days no gonococci could be found. For home treatment the patient was ordered vaginal douches of from 2 to 4 quarts of hot boracic or normal salt solutions taken in the recumbent posture. On June 20, there was no discharge or other symptoms of gonorrhea and the patient was discharged. On June 29 she was attacked with acute appendicitis, for which he operated and removed a sloughing appendix. For the subsequent five weeks, during which she was in bed in the hospital recovering from the operation, he made observations every few days of her genito-urinary organs and there was no symptoms of gonorrhea. The patient made an uninterrupted recovery and left the hospital. In discussing chronic conditions which result from a neglected or improperly treated gonorrhea, Dr. Loux stated that care should be exercised in adapting methods and means to avoid irritating the already damaged urethral structures. He emphasized the necessity of making routine use of the endoscope and determine its nature. Chronic follicular urethritis is readily recognized by endoscopic examination and by palpation of the enlarged follicles over a bougie, and is treated by gradual dilatation of the urethra by means of bougies, massage of the enlarged follicles, and by the local application of 25 to 50 per cent. argyrol solution to the individual enlarged follicles as revealed by the endoscope. This treatment is carried out three or four times a week and is by far the most satisfactory method he had ever found. Most cases of chronic gleet are due to ulcerative conditions of the urethra and in the management of these the endoscope is indispensable. After determining the exact location of the individual ulcerations the method of treatment depends upon whether the ulcerations are sharply localized or whether there is a coexistent general hyperemia of the urethra. In the former case, applications of 50 per cent. argyrol solution (through the endoscopic tube) to the ulcerations should be made at least three times a week. If general hyperemia exists, the use of mild astringents should precede the topical application of argyrol, in order to rid the urethra of the mucopurulent accumulations. From four to six weeks of this treatment, with care in the use of instruments, will heal the ulcerations and cure the gleet in the large majority of cases.

Another very common condition is the reduction in the lumen of the urethra by inflammatory exudate, occasioned by repeated attacks of gonorrhea or a primary case of long duration. In these cases, endoscopic examination shows the seat of beginning stricture and the presence of more or less localized inflammation. The management of these cases is extremely important because of the certainty of the occurrence of organic stricture unless the patient agrees to a several weeks' course of treatment. He should report every third or fourth day for the passage of bougies of gradually increasing sizes, followed, if active inflammation exists, by the deep instillation or topical application of 25 per cent. argyrol solution, depending upon whether the inflammation is circumscribed or more or less diffuse.

Dr. Loux summarized his paper as follows: Concerning acute gonorrhea, (1) he would strongly deprecate the treatment of acute anterior urethritis by means of irrigation, because of the danger of spreading the disease to the posterior urethra; (2) irritating injections of any kind should never be used in acute gonorrhea because of the certainty of occurrence of a mixed infection and the extension of the disease, by contiguity, to the urethral follicles; (3) argyrol, as a non-irritating gonocide, with a specific effect in allaying the symptoms of inflammation, is the drug of choice for injection, and may be used in any strength and at any stage of the disease; (4) astringents, such as zinc, hydrastin, bismuth and lead, should never be used in the acute stage of gonorrhea, but should be reserved for the post-gonococcus period when the urine remains shreddy; (5) these astringents should not be used in sufficient strength to cause the patient to experience pain or irritation. Concerning chronic gonorrhea: (1) Endoscopic diagnosis and treatment are indispensable as a routine measure; (2) silver nitrate or other caustic or irritating applications or instillations should be seldom used, and then only in the most skilled hands and with the greatest care; otherwise there are likely to occur structural changes in the urethra, predisposing to organic affections amenable only to surgical procedure.

The discussion of Dr. Loux's paper was opened by Dr. H. M. Christian, who stated that the methods mentioned were, in the main, those practised by himself. He stated that potassium permanganate is of no value in gonorrhea other than as a simple cleansing agent. Dr. Christian agreed with Dr. Loux that argyrol was undoubtedly the best gonocide known to-day. After having used that silver salt continuously for more than two years, he prefers it because it never irritates, it is rapidly destructive to the gonococci, lessens the discharge and shortens the duration of the disease. The speaker stated that it must be borne in mind that one has to deal not only with the gonococci, but with the destructive action of the microorganism as well; in other words, destruction of the gonococcus does not by any means imply of necessity the cure of the disease, as there always remains a condition of catarrhal urethritis which requires a particular line of treatment. If a case of gonorrhea is seen in the early inflammatory stage, where ardor urinæ and chordee are the most annoying subjective symptoms, Dr. Christian orders powders containing salol, sodium bromide, potassium bromide, each 2½ grains every two hours. At the same time a 5 per cent. solution of argyrol is ordered to be used by the patient as a hand injection three or four times daily, the solution being held in the urethra for ten minutes. If the patient can spare the time it is advisable to wash out the anterior urethra with several syringefuls of warm normal salt solution prior to using the argyrol injection; this line of treatment can be carried on through the second and third week. When the subjective symptoms subside, it is sometimes of considerable advantage to supplement the local treatment with the use internally of copaiba and sandalwood oil. Ordinarily at the beginning of the third week, the patient enters upon the stage of decline, or, as Professor Finger styles it, the "mucous terminal stage" of the disease. In a case going on to recovery, the discharge is now scanty, then mucopurulent in character and containing few if any gonococci and this is by far the most important stage in the treatment of the disease as regards the patient's future welfare; it is here that experience teaches that one needs more than a mere gonoccidal agent. In addition mild astringent lotions are needed to help restore the integrity of the damaged mucous membrane. A good plan now is to use 5 per cent. solution of argyrol night and morning, employing through the day some such astringent as zinc, bismuth, hydrastic, lead, berberine, etc. At the beginning of the fifth week when nothing remains but the well-known "morning drop" and the urine is clear but contains shreds, it is well to use the argyrol solution at night and to use once or twice through the day one of the well-known astringent mixtures. If in the second or third week the clinical symptoms and the two-glass test show involvement of the whole urethra, the treatment by hand injections is temporarily abandoned. Deep instillations of ten per cent. solutions of argyrol are then employed at short intervals until such time as the second urine becomes clear. This in general is the line of treatment that the speaker had used at the University of Pennsylvania and his other clinics for the past two years and is one that has given more satisfactory results than any hitherto employed.

Dr. Orville Horwitz condemned the irrigation treatment of gonorrhea and summarized his opinions as follows: The irrigation method of treatment will not abort acute specific urethritis; chronic urethritis and involvement of the deep sexual organs are common sequences; in many instances, in order to effect a cure in the terminal stage of the disease, the irrigation must be discontinued and other methods of treatment employed; irrigation should not be employed in the acute stage of specific urethritis; irrigation of the deep urethra by means of hydrostatic pressure is injurious in the majority of cases of acute gonorrhea, and is conducive to the development of complications; the best treatment today for gonorrhea is that by means of injection of argyrol solutions which are strongly antiseptic and non-irritating.

Dr. R. O. Kevin prefaced his remarks with the statement of the French surgeon Ricord, that "A clap begins and God alone knows when it will end." Fortunately, however, this statement is not as true as it was a few years ago. Dr. Kevin stated that with the use of twenty per cent. argyrol solution he had been able to cure 85 per cent. of his acute cases in from two to four weeks. He quoted Purdy, of London, who stated that since the introduction of argyrol into the enormous clinic at the London Lock Hospital, seventy-two per cent. of the early cases had been cured within a month and there had been no relapse after six weeks. Dr. Kevin had been associated with Dr. Loux for several years at the clinic and could corroborate his conclusions. The speaker stated that he had seen so many acute cases cut short that he always practised the abortive method when possible; this method is as follows: If the patient presents himself during the first forty-eight hours of an attack of gonorrhea, the anterior urethra is washed out with warm water or normal salt solution. Then two drams of twenty per cent. argyrol solution is injected into the anterior urethra and held there for ten minutes; this injection is repeated by the patient every three

hours, night and day, for three days. Even if this method does not abort the disease, it always effects a cure in a shortened period, and affords the patient entire freedom from the pain and irritation usually present in an early gonorrhea. If by this means the disease does not show signs of being aborted, Dr. Kevin practises the same methods mentioned by Dr. Loux.

The Radical Cure of Senile Hypertrophy of the Prostate.—Dr. Orville Horwitz read this paper, which is based upon a study of 145 operations performed by himself. He stated that the question under discussion has, with the possible exception of appendicitis, attracted more attention in the surgical world than any other subject. It is well-recognized that the danger to the patient with enlarged prostate begins as soon as it is necessary to resort to the daily use of the catheter and when this period arrives a surgeon should be consulted to supervise the case and decide what operative measures are desirable or necessary. It was emphasized that no one operation was suitable to all cases and that each patient is a law unto himself in the matter of choice of operation. The two operations which have stood the test of experience are prostatotomy by means of the galvano-cautery (the so-called Bottini operation) and prostatectomy. The speaker stated that the Bottini operation is extremely valuable, safe and always to be preferred to cutting operations in suitable cases. Out of 98 cases operated upon by the author, by the Bottini method, three died, two of uremia, and one of sepsis; all three were very old men. Twelve cases were lost sight of after leaving the hospital but were much improved when last examined. This leaves 81 cases concerning which there was obtained definite knowledge as to results. The ages of the patients varied between fifty-two and eighty-one years. The speaker stated that his statistics proved conclusively that the earlier the patient submitted to operation, the better the results. Of the total 81 Bottini operations all the patients were either entirely cured or very much benefited; four required second operation, and a considerable proportion were treated for several months subsequently for accompanying chronic cystitis. Prostatectomy, the speaker stated, is regarded as a valuable operation but authorities differ as to when and how it is to be performed. As many as 20 different operations have been suggested. Here, too, the individual case decides methods, choice of operation, etc. The prostatectomies performed by the author were as follows: 3 complete (suprapubic incision); 6 complete (combined suprapubic and perineal incisions); 7 partial prostatectomies (suprapubic incision); 34 complete perineal prostatectomies. Of the 9 complete suprapubic operations, two died, one of suppression of urine, one of uremia. In all the cases, convalescence was slow; in five cases the ultimate results were all that could be desired. Of the 34 perineal prostatectomies, six died from uremia, sepsis or shock; 6 cases were lost sight of after leaving the hospital; 16 were cured, four markedly benefited, one unimproved.

Dr. Horwitz summarized the results of observations in his 145 operations as follows: (1) A routine method is not applicable to the treatment of prostatic hypertrophy; every case is a law unto itself and the treatment will depend on the various conditions presented in each individual case. (2) The dangers attendant on the daily catheterism are greater than those of a radical operation performed at the onset of the symptoms caused by the obstruction. (3) The proper time to perform a radical operation is reached as soon as it becomes necessary for a patient to resort to daily catheterism. (4) The gratifying results obtained by a number of the operations in many cases demonstrates that the Bottini operation is one of great surgical value. It is applicable to a large percentage of cases; which if properly selected has proved to be the safest and best method of relieving an obstruction caused by prostatic hypertrophy. In those cases in which a stone in the bladder is associated with a prostatic enlargement, lithoplaxy may be performed in conjunction with a galvanocautery prostatotomy. (5) A complete prostatectomy is justifiable if performed early before the individual is broken down in health and secondary complications have supervened. In early operation the results are most satisfactory, recovery rapid, the mortality varying between five per cent. and seven per cent. (6) A complete prostatectomy in feeble elderly patients with long-standing obstruction and secondary complication, the prognosis is grave and the mortality ranges between 15 per cent. and 18 per cent. If the bladder in the cases happen to be hopelessly disabled, the results obtained by the operation are negative. Cases of this description are only suitable for suprapubic drainage. (7) In 90 per cent, of all cases the gland can be readily removed by means of a medium perineal incision. The perineal operations recommended by Bryson is considered the operation of choice. (8) Complete suprapubic prostatectomy is shown to be more dangerous than the perineal operation for obvious reasons. A suprapubic prostatectomy is safer if combined with perineal drainage. (9) Partial suprapubic prostatectomy is indicated in such cases as where a valve-like lobe exists which interferes with urination, or where there is a partial hypertrophy of one of the lobes. (10) A perineal prostatectomy is best suited for those cases where the enlargement of the lateral lobes has a tendency to progress toward the rectum, to obstruct the urethra, or project backward into the bladder. (11) A prostatectomy is always attended with more danger than the Bottini operation and the convalescence is more prolonged. In suitable cases the latter operation is therefore the one of choice.

Dr. Edward Martin agreed with Dr. Horwitz that, if operation has been advised and consented to, the circumstances of the individual case decided which of the several operations is to be performed. He believed that the Bottini operation has proved of great value and is preferable to cutting operations in suitable cases. He did not, however, advise operation in all cases of enlarged prostate. He recognized the inconveniences and dangers attendant upon the daily use of the catheter, but believed in the value of palliative measures in the majority of cases. He recommended care in the selection of catheters and chose one that enters the bladder with the least force and least pain to the patient. If a soft rubber catheter cannot be introduced, a woven elbowed one is to be chosen. If obstruction or spasm necessitates habitual resort to a metal catheter, surgical intervention is required. When patients use the instrument upon themselves, the hands should be washed thoroughly, dipped in bichloride solution, the meatus washed with the same solution, and be provided with an irrigating bag containing one pint of hot argyrol solution, 1 to 1,000. Infection of the bladder is commonly present and should be treated by means of bladder irrigations. For this purpose a fountain syringe, supplied with a catheter, should be suspended two feet above the level of the bladder. The anterior urethra is first thoroughly flushed, after which the catheter is pushed into the bladder and the urine withdrawn. The flushing of the bladder is continued until the return flow no longer contains pus or mucus. The temperature of the argyrol solution employed should be of the temperature of the body or a little above it. When practicable this antiseptic flushing should be done each time the catheter is passed. If this treatment is inefficacious continuous catheterization becomes necessary. For this purpose a

large, soft rubber catheter, or a self-retaining one, is selected and the antiseptic solution introduced; if the catheter is properly introduced, the entire amount of the solution will return. Twice a day the urethra and bladder are thoroughly flushed with the antiseptic solution, the catheter being withdrawn far enough to allow the injected fluid to escape from the meatus, and then being pushed back into its former position. The success of this treatment depends upon securing free and continuous drainage and this is incident to the permeability of the catheter and its retention in the proper position. When skilfully applied it is one of the safest and most successful means of treating cystitis, which so frequently complicates obstruction from prostatic enlargement.

BOOK REVIEWS.

Subjective Sensations of Sight and Sound, Abiotrophy and Other Lectures. Second Series. Lectures on Diseases of the Nervous System. By Sir William R. Gowers, M.D., F.R.C.P., F.R.S., Hon. Fellow Coll. Phys., Ireland; Member of the Soc. Medicins Russes of St. Petersburg and of the Royal Soc. of Science of Upsala, etc. P. Blakiston's Son & Co., Philadelphia.

It is almost needless to say that this series of lectures is extremely interesting and suggestive. No one can read any of them without being stimulated to the making of observations for himself along similar lines, and that, rather than the mere feeling of information acquired, is the true test of the value of a medical essay. For the specialist in mental diseases the essays on Subjective Visual Sensation and Subjective Sensation of Sound will prove particularly valuable. The essay on Syphilitic Diseases of the Nervous System, thoroughly conservative as it is, enunciating certain principles that are of the greatest practical usefulness, deserves to be read not only by the specialist in nervous diseases, but by every general practitioner, for, unfortunately, the beginnings of syphilis of the nervous system must be seen and treated by the practitioner first and are only too often missed or neglected. It is interesting to find that Sir William does not believe either in the large doses of some of the American school or the prolonged treatment of the French school of Syphilologists, yet his conservatism is supported by excellent reasons.

A Manual of Medicine. Edited by W. H. Allchin, M.D.Lond., F.R.C.P., F.R.S.Ed., Senior Physician and Lecturer on Clinical Medicine, Westminster Hospital, etc. Vol. 5. Diseases of the Digestive System and of the Liver; Diseases of the Peritoneum and of the Vessels of the Abdomen; Diseases of the Kidneys; Diseases of the Ductless Glands. The Macmillan Company, New York.

We have already spoken of the extremely handy size of the volumes in Dr. Allchin's Manual on Medicine. Cumbersome tomes may be absolutely necessary at times, but they certainly are not convenient. The present volume contains especially the diseases of the digestive organs. Special attention is paid to the mouth and its various affections, an important area of the digestive tract, since the impression has gained ground that there is much more danger from neglecting pathological conditions in the mouth than was formerly thought. With regard to the three conditions, vomiting, diarrhea and constipation, which physicians are oftenest called upon to ascertain the meaning of and to treat, there are twenty very practical pages typical, one would say, of the English direct, concise, yet complete method of dealing with such subjects.

Besides disorders of digestion other affections of the abdomen are treated in this volume. Recent progress with regard to the diseases of the liver and of the kidney is brought out admirably. Considering that all of this material is crowded into less than seven hundred comparatively small pages, it is surprising to find how little of the sensation of crowding or hurriedness is experienced in reading the volume. The condensation necessary to accomplish this has been done very, very well, and Allchin's Manual promises to make for itself a definite place in English-American medical literature.

The American Pocket Medical Dictionary. Fourth Edition. Edited by W. A. Newman Dorland, M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania. W. B. Saunders & Company, Philadelphia, New York, London.

The appearance of the fourth edition of this invaluable work hardly needs extended review, but it would be impossible to pass it by without adding a tribute to its worth and excellence. In its new form it will be found more useful than ever before, and those few members of the medical profession who have been able to dispense with it in the larger edition can hardly fail to feel the need for such a handy volume. Not only is its text accurate and up-to-date, its illustrations copious and a real illumination to the reader, often sorely perplexed by misleading pictures and diagrams, but its appearance is so attractive and its size so convenient that we feel sure there will soon be many to declare that they "could not keep house without it."

Biochemical Researches. Collected Reprints of Publications from the Laboratory of Physiological Chemistry of Columbia University. By William J. Gies and collaborators. Vol. 1. Columbia University.

Some 40 reprints are here brought together, with some published abstracts of preliminary reports of investigators into a highly representative volume that reflects great credit upon the editor.

The papers have appeared in scientific publications and it is a great service that is here rendered in their collective binding. We hope that Dr. Gies may continue to be the stimulus for younger men in work in physiological chemistry and that he may be able to further the cause of scientific medicine by other volumes from his laboratory.

Auto-Intoxication. Part IV. of Clinical Treatises on Disorders of Metabolism, Pathology and Therapy. By Carl Von Noorden, Physician-in-Chief to the City Hospital Frankfort-A.-M., Germany. E. B. Treat & Co., New York.

In this little volume Professor Van Noorden has once more proved his originality in the handling of a difficult but important subject. The phases of auto-intoxication treated are those connected with the acid products of metabolism, especially in diabetic conditions. Those who are interested in diabetes will find interesting and suggestive discussions of the sources of the acetone bodies, and of the question, Where are the acetone bodies formed? While suggestive, some of this work must wait for confirmation at the hands of other observers.

Elements of Surgical Diagnosis. By A. Pearce Gould, Surgeon to the Middlesex Hospital, etc., London. Third edition. W. T. Keener & Co., Chicago.

For the third edition of this practical little work, the whole text has been revised, much has been rewritten, and many additions have been made with the hope of

adding to its usefulness. The revision has taken into account how much the art of surgical diagnosis owes to the advances in the knowledge of bacteriology, skiagraphy and hematology. In addition to other material a chapter has been added on the diagnosis of certain acute abdominal diseases for which surgical aid is now sought. The author has separated the diagnosis of injuries from that of diseases, as it seems to him to possess the advantage of greater simplicity, although not in strict accordance with the ways of nature. The only omission is the total lack of illustrations. The work is well written, in a concise pointed style and thoroughly covers its allotted field. The index is complete and satisfactory.

The American Year-Book of Medicine and Surgery. A yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, and Textbooks of the Leading American and Foreign Authors and Investigators, collected and arranged with critical and editorial comments by J. M. Baldy, M.D., Samuel Horton Brown, M.D., J. Chalmers Da Costa, M.D., W. A. Newman Dorland, M.D., George Fetterolf, M.D., John H. Gibbon, M.D., Virgil P. Gibney, M.D., C. A. Hamann, M.D., Barton Cooke Hirst, M.D., D. Braden Kyle, M.D., Walter L. Pyle, M.D., J. Hilton Waterman, M.D., under the general editorial charge of George M. Gould, M.D. Surgery. W. B. Saunders & Company, Philadelphia, New York and London.

This volume covers the field of Surgery, Obstetrics, Gynecology, Orthopedic Surgery, Ophthalmology, Diseases of the Nose, Throat and Ear and Anatomy, giving a summary of the more noteworthy advances and discoveries made during the past year and does more than is usual in such works, to give the profession a clear idea of what is of real value in recent medical literature of the world. More than half the space is given to General Surgery, and while references are made to the original publications, thus enabling one to follow up more in detail any subject discussed, it is a pleasure to read the reviews given and to get a tangible idea of the investigators' work. In many instances the technic of operative procedure is given in full with citation and complete analyses of cases treated and the author's conclusions therefrom, thus rendering it unnecessary for the general reader to pursue further the subject under consideration.

The same statements are true of the other subjects treated, so that we regard the volume as an exceedingly valuable addition to the library of any who wish to become well informed in the most advanced methods of treatment by acquiring a knowledge of what has been done along advanced lines of investigation.

It is a well bound volume and the illustrations, excellent and well chosen, greatly enhance the value of the text.

A Reference Handbook of the Medical Sciences. By Various Writers; Edited by Albert H. Buck, M.D., Vol. 7. Sac-Ulc. William Wood & Company, New York.

In sight of the end of this admirable reference work—a library in itself—we congratulate, editor, contributors and publishers alike on the successful accomplishment of a truly remarkable task. Synonyms fail us in further praise of the Handbook. Six times have we given the work unstinted commendation and we lack appropriate phrases to give it again in new form.

Some attention may be called to a few of the articles that are specially commendable. Such are those on Secretion, Septicemia and Pyemia, Serum Diagnosis and Therapy, Sewerage, Sexual Organs, Spectacles, Spermatozoa, Spinal cord and its Diseases, Spine, Spleen, Stomach, Sympathetic Nervous System, Syphilis, Teratology, Trematoda, Tuberculosis, Tumors and Typhoid Fever. These are among the more important longer articles, but many of the shorter articles are entitled to equal characterization.

A Practical Treatise on Nervous Diseases. By S. Savary Pearce, Professor of Nervous and Mental Diseases in the Medico-Chirurgical College of Philadelphia. D. Appleton & Company, New York and London.

This work should be classed as one of the many smaller manuals of the purely descriptive type that are of great service to the student-body in their initial introductory to the study of nervous diseases. As such we believe that it will serve a very useful function.

For the practitioner, however, and even for the more thorough class of student, we do not think it as well adapted as many other works of the same class and description. We make this comment because of the fact that the work strikes us as incompletely thought out. There is a lack of logical continuity in the mode of descriptions. Many related diseases being separated, even in different chapters—and many unrelated disorders being considered in sequence.

The value which the anatomical structure of the nervous system makes logical arrangement of symptom-complexes possible is here, we believe, entirely lost sight of—making, to our mind, a nervous hodgepodge rather than a consecutive handbook.

A Compend of Gynecology. By William H. Wells, M.D., Chief of the Gynecological Staff of the Mount Sinai Hospital, Philadelphia; Demonstrator of Clinical Obstetrics in the Jefferson Medical College, Philadelphia; etc. Third Edition Revised, Enlarged with 145 illustrations. P. Blakiston's Son & Co., Philadelphia.

The value of this most excellent little quiz-compend is established by the fact that it has successfully entered its third edition. A section on the general therapeutics of gynecology has been added in this edition, thereby making it a most complete publication of its kind.

Many new plates have been inserted and, contrary to the usual illustrations in quiz-compends, they are explanatory rather than puzzles to the students.

We can most heartily recommend this little compend as a helpful adjunct to the gynecological text-books.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

La Torsion du Cordon Spermatique. Lr. LaPointe. 12mo, 180 pages. A. Mallione, Paris.

Obstetrics for Nurses. By Dr. J. B. DeLee. 8vo, 460 pages. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

Progressive Medicine. March 1, 1904. 8vo, 338 pages. Illustrated. Edited by Dr. H. A. Hare. Lea Brothers & Co., New York and Philadelphia.

SPECIAL ARTICLE.

BELLEVUE HOSPITAL—THE OLD AND THE NEW.*

THE history of Bellevue Hospital goes back to an epidemic of yellow fever which occurred in New York in 1794. To us of this generation it seems almost impossible to conceive of yellow fever raging virulently as far north as New York, but it must not be forgotten that at the end of the eighteenth and the beginning of the nineteenth centuries epidemics of yellow fever were very frequent along the Atlantic coast, even as far north as Boston. At one time it was actually declared, by a committee of authoritative medical men who investigated the situation, that Philadelphia would have to be abandoned eventually as a site for a great city because of the frequency with which this disease ravaged the population. Its appearance was always followed by the yellow fever scare and in 1794 the fears of the inhabitants of New York, and especially the conviction that the disease would surely recur again the next summer because that was always the rule in the epidemiology of those times prompted the authorities to do something in order to lessen the danger of the spread of the disease. Dr. Carlisle, in his account of Bellevue Hospital, published by the Society of the Alumni of Bellevue Hospital, New York, 1893, gives the origin of the name Bellevue and the conditions of its original purchase as follows:

"It was the beginning of the worst yellow-fever period the city had experienced. The State government had represented to the city authorities the necessity of providing some place of isolation for persons afflicted with the malignant fever. The most eligible place that presented itself was that belonging to Mr. Brockholst Livingston, and situated on the East River, 'opposite the three-mile stone.' It was then held under lease from Mr. Livingston by Nicholas Devise. This lease was to run for six years, with the privilege of purchase for £2,000. In view, therefore of the exposed condition of the city, and in order to allay the fears of the citizens, it was determined to purchase this lease. Mr. Robert Lenox, in behalf of the board, concluded the purchase in 1794. This plot was about five acres in extent, and had been once a part of the Kip's Bay Farm. It was conveyed by Jacobus Kip about the year 1765 to Peter Keteltas; by him to Martin Hoffman, and by him in turn to Robert Leake, in 1772. Leake gave to the place the name of Belle View. In 1781 it was again sold, and in 1783 it came into the possession of Lindley Murray. The latter gentleman, while residing in England in 1793, whither he had retired at the close of the War of Independence, conveyed this property through his attorneys to Mr. Brockholst Livingston, who retained the name but with a different spelling,—Belle Vue,—and this is the genealogy of the name."

The principal building existing at that time on the plot thus secured was a two story and attic structure. This was not ready for occupation until the fall of 1794. Always with the first frost yellow fever declines and then promptly disappears, so that there was not much use for the newly acquired property during this first year. As anticipated, however, the fever occurred very early the next year and before the end of May some sailors had been transferred to Belle Vue (spelled as two words, in those times, the second one with a capital), by the health officer of the board. Some idea of the awful way in which the disease raged during this summer may be gathered from the fact that the deaths from yellow fever numbered 732, out of a population of less than 30,000. Hospital accommodations were incomplete, as is very likely to be the case in a rapidly growing town subject to all the dangers of an introduction of infectious diseases by the arrivals of vessels of all kinds, and so there came the first accounts of complaints with regard to Bellevue, which, as good New Yorkers we are sorry to say, have practically continued with certain noteworthy intervals of interruption ever since.

The next year the yellow fever did not come so early. Dissatisfaction with the mortality records of Bellevue and the hope that a more airy location and one farther removed from the city itself might prevent the spread of infection, led to the selection of Bedloe's Island as a place for the erection of a new pest house, and this was used as a quarantine station. The beds and bedding which had been used the year before at Bellevue were taken to this hospital, which was under the control of the State. The health officer of the time, Dr. Richard Bailey, complained in a report to Governor Jay that these articles were in a very filthy state, and that within eight days after they were brought from Bellevue those who had transported them, together with the nurse and the stewards of the house, were attacked with fever, the attending physician, Monsieur Bouvier, also being indisposed for several days.

Bellevue became a hospital again in 1798, as a result of the worst epidemic of yellow fever the city ever knew. There were over 2,000 deaths during the summer and fall of 1798 out of a population of about 60,000. In his account of Bellevue Hospital, Dr. Carlisle gives, on contemporary authority, the report namely of Dr. I. S. Douglass to John Oothout, Esq., Chairman of the Commit-

* We are indebted to the Society of the Alumni of Bellevue Hospital, through the courtesy of Dr. Robert J. Carlisle, for a number of the illustrations embellishing this article.

tee, as published in the *Medical Repository*, December 17, 1798, the details of this matter:

View from the Southwest about 1845.

"Belle Vue was opened on June 12, 1798, under the care of Dr. Isaac S. Douglass. From that date to November 14, 389 patients were admitted, perhaps three-quarters of whom were sick with pestilential fevers. There were sixteen nurses employed. Dr. Douglass himself contracted the disease, but he traced the infection in his case to his having visited friends in New York and having slept in a highly infected part of the city. Three days after his return to Belle Vue he was seized with a fever. He ultimately recovered, and in December of that year he was asked by the Health Commissioners to trace the source of infection in his own case. In his reply he gives some interesting facts in regard to the interior arrangements of the hospital: 'The health office boatmen who were in the habit of bringing the sick to Belle Vue from the city and shipping were accustomed to enter the hospital at all times, and to assist in placing as well as moving the sick from room to room. The number of the washerwomen during this period was seven. Several persons were employed constantly in cooking, cleaning, and in burying the dead. There were besides transient people, near relatives of the sick, who were permitted by the Commissioners to visit occasionally. Several persons accompanied their friends to Belle Vue, stayed with them and nursed them during their illness. Under all these circumstances there happened to my knowledge no instance of infection, although an opinion has been adopted by many that my sickness, whilst residing at Belle Vue Hospital, arose from infection imbibed at that place. . . . In making this declaration, I must remark to you that the situation of the medical attendants at Belle Vue was by no means a propitious one. Before the new buildings were erected for the accommodation of the sick, the physicians' room (the only one they had) was literally surrounded by them (the sick). The room adjoining the front and back piazzas, the hall, the rooms and hall in the second story, a room in the cellar that had been used for a kitchen, all contained sick. They were likewise placed in several Chinese summer-houses in the small space between the main house and the East River; and in the building erected for the purpose of a bathing-house. A large canvas was also erected (for want of a more convenient place) under the windows of the southwest part of the house for the reception of the dying and the dead. Under all the disadvantages enumerated, I know of no instance where infection resulted.'"

It is curiously interesting to find this anticipation of modern knowledge with regard to the non-infectiousness of yellow fever by ordinary contact, but if observations had been carefully made such would have been found to be the case by others. It is interesting but not very encouraging to find also that Bellevue Hospital at that time furnished opportunities for the study of infections of various kinds, extending even to the possibilities of physicians becoming infected because of the crowded way in which patients were housed and the cramped and narrow quarters allowed to overworked medical men. We might consider it due to the crudeness of the times and the one thing that one might be sure would not occur in a modern New York hospital would be just this overcrowding and its results, and yet this is the worst source of complaint with regard to the hospital at the present time.

The city realized the necessity for having the property as its own instead of renting it and so in 1798 it was bought for £1,800 sterling. For several years after its purchase there is no account of the reception of patients at Bellevue, but in 1803, as the result of another yellow fever outbreak, during which 700 deaths occurred in the city, nearly 200 patients were received into the hospital. Very few of these were natives or residents of New York, most of them being recent arrivals, immigrants principally from Ireland and Germany. The condition of affairs at the hospital can be best realized from the mortality statistics, the number of deaths during the summer and fall just equaled the number of recoveries. In 1805 Bellevue was handed over to the Health Department and was used for the last outbreak of yellow fever which occurred for some fourteen years. Notwithstanding these awful epidemics of fatal disease, the city continued to

Vicinity of Belle Vue in 1803.

grow, and in 1805 had over 75,000 and in 1810 had reached nearly 100,000 in population.

In 1811 it was considered necessary to secure a large site for the almshouse and hospital purposes and as a large plot of ground just next to

the house that had been used as a fever hospital at Bellevue could be obtained it was purchased. The property thus secured by the city is the present site of Bellevue Hospital and was bought from the heirs of the Kip family, having formerly constituted a part of the old Kip's Bay Farm. The committee which was sent by the Common Council to negotiate for the property was empowered to purchase the site at a price not exceeding $3,500 an acre. It was on this basis that the sale was made, the survey made by the city surveyor showing that the plot contained slightly over six acres. The liberal foresight displayed by the city authorities at the time was undoubtedly due to a large extent to the broad-minded sense of municipal obligations toward its citizens existing in the mind of the Mayor De Witt Clinton, and his action in this special matter seems to have been influenced to no slight degree by his associations with Dr. David Hosack, who was doing so much at that time to organize charities of various kinds in New York City. The old Kip estate, of which the Bellevue grounds were a part, contained originally 150 acres on the East River, extending from what is now about Forty-first street down to Twenty-sixth street. As there was a hollowing out of the river coast line here this portion of the East River came to be known as Kip's Bay, and the whole tract of ground as Kip's Bay Farm.

The Kips were descendants of Hendrick Kip, a thrifty tailor who came from Holland to the City of New Amsterdam some time about 1640.

In selecting this really very fine location for its almshouse and hospital, or rather for what afterward came to be considered its Department for the poor and for ordinary criminals, for prisoners were also to be housed in it, New York City was only following out the tradition of the liberal municipal generosity in the treatment of its poor that had characterized New Amsterdam from the very beginning of its existence. Even when the city had less than one thousand inhabitants there was a hospital in connection with its poor house and this was, by the way, the first hospital built upon the soil of what is now the United States. This was established toward the end of 1658 and existed down to 1680, when there is a record of the selling of what was known as the "old hospital," or "five houses," to be found in Toner's Medical Men of the Revolution.

As is noted by Dr. Carlisle at the end of the seventeenth century New York, though a mere village of 4,300 inhabitants, contributed for the support of her poor proportionately nearly one-half as much per capita of population as did London at the same time, which had at this period a population of nearly three quarters of a million and was considered one of the greatest cities in the world. He notes also that this expenditure was not the only source from which the indigent could draw relief. Besides the money provided by the municipal poor tax, which amounted to nearly $800 a year, a large amount was contributed by the Church, which had good endowments and was liberally supported by the members.

The first Poor House in New York, which is of interest to us in connection with Bellevue as the City Hospital because it contained a ward for the sick poor, was erected in 1735. Its site was that upon which the City Hall now stands. The instructions adopted by the Common Council for the Committee which was to oversee its construction, show once more the liberal spirit in which the old-time City of New York faced its municipal

The First Poorhouse in New York, 1736.

duties in this matter. Enough land was to be obtained so that the building might have a good yard and garden attached to it. The building was to be of good size for those times and the material was to be of stone. It was 56 feet long, 24 feet wide and two stories high with a cellar. The ward for the sick poor was about 25 feet square, situated on the upper floor on the Broadway side of the building and represents the first hospital accommodations provided within the limits of the present New York City.

This building was so substantial and well built that later on, when it was abandoned as a poor house and hospital it was readily converted to

Vicinity of the Poorhouse, 1763.

other uses and became the famous Scudder's American Museum for several years, while the Academy of Arts and the New York Historical Society also had rooms in it. The name of the New York Institution was given to it and such other charitable and educational interests as the Lyceum for the Deaf and Dumb and Professor Griscom's chemical lectures, a sort of popular course in chemistry in those days, were allowed quarters and all rent free.

It is interesting, too, to find that the first visiting physician at this original hospital in New York was a worthy predecessor of the distinguished medical men who have since occupied such positions in care of the city's poor. He was a pupil of the famous Boerhaave who had introduced the clinical teaching of medicine to the world and had practically revolutionized the medicine of his time. This first visiting physician in New York was Dr. John Van Beuren, a graduate of the Medical School in Leyden. Two of his sons, Beeckman and Abraham Van Beuren, were also physicians, the latter being the grandfather of the late Professor William H. Van Buren, the family having dropped the 'e' of the name in the interval.

It is not surprising, then, from what we know of the early history of New York's attempts to accommodate its poor, that, after the purchase of a magnificent location on Kip's Bay, the erection of a very substantial and even handsome building with all the architectural advantages considered necessary at the time was determined upon. During the year 1811, after the purchase of the ground, rapid progress was made in the building so that before the end of the year, nearly $50,000 had been expended. In 1812 came the war with England and the Common Council ordered the building committee to spend as little as possible though it did not positively require the work to be stopped. It was, therefore, not until 1816 that the main building of Bellevue Hospital, almost as we know it now, with the exception of the upper story and some of the pavilions at the rear, was finished.

At the end of April, 1816, the buildings were announced as ready and a formal opening ceremony was arranged. This was held on April 29, at twelve o'clock. The building was originally completed in three stories. It was 325 feet long, by 55 feet wide running not quite directly north and south with a north and south wing each 100 feet long by 55 feet wide.

This main building, however, was intended more especially for the poor and two special pavilions, 75 feet long by 25 feet wide, almost on the lines respectively of the present Twenty-eighth and Twenty-sixth streets were erected for hospital purposes—the northern one for male patients the southern for female patients.

Besides the absence of the unoccupied ground around the hospital, only one feature of the present situation of Bellevue would strike an inhabitant of New York of those days as very different from that which exists at the present time. What is now the main hospital building was then much nearer the river. The high water line came up to within a short distance of First Avenue. Otherwise things are mainly unchanged, the additional story that has been added to the main building at Bellevue, changing its appearance very little, as can be seen from the views given of the building as it appeared in those days.

The total cost of the institution as reported on its completion at the beginning of 1818, was about $425,000. The whole was enclosed by a stone wall, ten feet in height, and it was known as the Bellevue establishment. The grounds of the institution had been extended before the erection of the wall, so that they reached approximately as far as Second avenue on the west and Twenty-eighth street on the north, and ran as far south as Twenty-fourth street. The southern portion had formed a part of the old Rose Hill farm and was purchased in 1818. The name Rose Hill is still used in connection with this part of the town in certain ways, though the recollection of its origin is gradually fading away.

Before a decade had passed such was the growth of the city that it began to be realized that the almshouse and the hospital could not be accommodated at Bellevue and especially not if proper attention and sufficient room was to be given to the sick poor. Accordingly Blackwell's Island was purchased by the city and in 1828, after the erection of buildings on it, first the prisoners and later the paupers were transferred to it. The building had scarcely been given up entirely to hospital needs when a series of epidemics took place during which a number of doctors and medical students laid down their lives. In 1846, John James Lawrence, a medical student, died of typhus. In 1847, Drs. Porter and Van Buren went the same way. During the same year eight other resident physicians took the disease, but fortunately recovered. In 1848, no less than seven physicians died at their post; caring for typhus patients. Their names are on a glorious list of honor and deserve to be recalled every time that the history of Bellevue is spoken of. They were Beals, Blakeman, Cahoon, Green, Hedges, Seligman and Worth.

A sad piece of political history marred the Bellevue grounds in 1845. To quote Dr. Carlisle, "'the city's stepfathers,' as Dr. Francis has wittily dubbed the gang that went popularly under the name of The Forty Thieves, looked with envious eyes on the almshouse property and Bellevue received closer scrutiny than she had for thirty years before." This interest was, however, for selfish reasons. It was realized that a good political job could be made out of the sale of unoccupied land in and around the Almshouse. Accordingly all the region now extending from Second avenue to First avenue and from Twenty-sixth to Twenty-eighth streets, besides the land from Twenty-fourth to Twenty-sixth streets, lying along the river and west to Second Avenue, altogether nearly twelve acres, was cut up into building lots and sold at public auction. The public auction was a farce and the lots were bought in by those in the ring, who made a handsome sum of money. This sadly crippled the future of Bellevue and is a lasting disgrace to the city authorities of the time.

Perhaps the saddest part of this portion of the history of Bellevue is the fact that several medical schools offered to become purchasers of portions of this ground for the sake of the clinical facilities which the proximity to Bellevue would afford

them, but every offer on their part was rejected, because the publicity of the sales would almost surely reveal how much money the gang was making by this steal from the city. Since then, of course, Bellevue has been confined to its present much narrower quarters and the development that would surely have come long before this, only for the fact that more land was not available in the neighborhood, was prevented. It is this wrong that New York has ever since owed to itself to right.

The first important change in the old building at Bellevue came in 1854 when the wing extending eastward from the north wing of the old building along Twenty-eighth Street was erected. On this some $60,000 in all were expended and it was made four stories high, in anticipation of the raising of the rest of the building another story, the main hospital buildings, and though at the time the buildings were already nearly half a century old the medical and surgical staff of the time by their devotion of every energy to the work succeeded in making the hospital one of the model institutions of its kind throughout the world. It was not until after the introduction of antisepsis, and then later of aseptic methods, that the hopelessness of making such old buildings, originally built for living purposes alone, suitable for modern surgical purposes that physicians and surgeons realized the handicaps under which they worked.

About this same time an important addition was made to Bellevue in the shape of a pathological museum. This was due largely to the energetic enthusiasm of Dr. James R. Wood, and the building was determined upon in 1853, though

Bellevue Hospital in 1879.

which it had been determined must shortly be done. This new portion was formally opened April 23, 1855. The difference in the times between the original opening and this occasion was marked by the absence of any religious ceremonies in the second and by the fact that the principal address was delivered by the President of the Medical Board, Dr. John W. Francis, who was one of the most prominent physicians of the city and a President of the Academy of Medicine.

The next year, 1856, saw the completion of the project to add an additional story to Bellevue, but also saw a more important addition in the erection of an amphitheater for clinical teaching in medicine and surgery, capable of seating 600 persons. This was the most commodious operating theater in the United States at the time. Since 1856 there have been practically no changes in not completed for some years afterward. It was of brick, two stories high and the upper story was used as a pathological museum and also a lecture room on pathological subjects. It replaced the old dead-house, which had been for many years an eyesore on the ground and had come to be more than a suspected source of some of the infectious conditions that developed in the hospital. To the museum Dr. Wood presented a magnificent collection of pathological specimens, hence it bears his name and as it has been added to by many members of the Bellevue staff, it has become one of the most interesting pathological collections in the world.

In 1849, the Medical Board had resolved that it was unfortunate to allow the magnificent clinical opportunities for medical teaching at Bellevue to go unused. Some teaching was accordingly ar-

ranged for and after the improvements made in 1855-56 and the completion of the pathological department in 1857, this became regularly organized and took special importance as a department of the hospital. It was not until March, 1861, however, that definite arrangements were made for the establishment of a regular medical school and not until April of the same year that permission was granted by the Commissioners of Charities and Correction to erect a medical school building within the hospital enclosure.

In this same year, 1861, a series of typhus epidemics began, and, as is noted by Dr. Carlisle, for the seventh time in its history Bellevue physicians nobly responded to the calls made upon their time and strength and stood at their posts, though members of the house staff sickened and died. The disease began its ravages in 1863 and took with it Drs. Cook and King. In the following December and January, Rowe and Olmstead followed them. In April, 1864, Devlin and Dewey were martyrs to duty. Out of twenty-one members of the staff, fourteen contracted the disease and of these, six, as we have said, died.

Since 1860 the principal additions to Bellevue have been in the shape of pavilions and annexes and it is interesting to realize that these have been mainly the gifts of private individuals. The first one, called the Sturges' Pavilion, was built in 1879 and is intended for the accommodation of such patients as have just undergone capital operations. It is located just south of the northeast wing and runs parallel to it, being one story in height with a mansard roof. A second pavilion, somewhat resembling in outward appearance the Sturges and lying parallel to it, was built in the same year, 1879, by the Commissioners of Charities and Correction on the Twenty-sixth Street side of the grounds, and, because of the purpose for which it is designed, is known as the Insane Pavilion.

In 1883 a private benefaction once more made a distinct addition. It was erected by Messrs. F. and H. Marquand in memory of their brother, Josiah Penfield Marquand. The rear portion of this is occupied by a kitchen and rooms for the isolation of children suspected to be suffering from infectious disease, the character of which has not yet been determined. The rest of the building is divided between women and children. Four years later, in 1887, Mrs. Richard H. L. Townsend erected the Townsend Pavilion. This is some seventy feet in length, smaller than the other pavilions, and is for the use of the gynecological department. In 1890 Miss M. H. Dehon, at a cost of $6,000, built what is known as The Annex, consisting of a suite of seven rooms and an operating room at the west end of the Marquand Pavilion. The next year, Miss Josephine Lazareth obtained permission to build four rooms on the east end of the Marquand Pavilion, in order to provide accommodations for graduate nurses of the school who fell ill and who up to that time had been compelled to find places in other hospitals.

In 1892, one of the most important of recent improvements was in the erection of the new Alcoholic Pavilion, which is at the east end of the north wing, lying parallel to Twenty-eighth Street. As there is no other hospital in the city which receives these patients, Bellevue has to treat many thousands of them each year and this department of the hospital was very sadly needed.

It will thus be seen that Bellevue is a heterogeneous collection of buildings bearing no structural relation to one another, erected to fill the urgent need of the moment, often felt to be makeshifts and yet, under the condition of affairs that existed with no chance of any more coordinate method of improving and enlarging the hospital. The main building, the principal part of New York City's housing provision for its sick poor, comes down to us from nearly a century ago Even the improvements made about half a century ago were necessarily designed on lines entirely that made them accord with the old-fashioned plan. Whenever Bellevue has been under the care of a Medical Board it has done good work, while, whenever it has fallen under political influences, results have been only too sad for the poor and only too costly for the city itself.

The most important change that has come for Bellevue in recent years has been the amendment of the city charter, which took the management of Bellevue Hospital, including the other city hospitals, Gouverneur, Harlem, Fordham and the Emergency Hospital for Women out of the hands of the Department of Charities and vested it in a Board of Trustees to be appointed by the Mayor, and who were to serve absolutely without compensation. These trustees were to be seven in number, the term of office to be seven years, with rotation that gives opportunity for one new appointment each year. This system has brought Bellevue under the same form of management as is now enforced for private hospitals in this city and in most of the other cities of this country.

Already the city hospitals have gained much from this new system. There is no doubt, however, that much more may be looked for from it. The recent proposal to replace the century-old building by a new, modern hospital building is what might be expected from a board of trustees who have the best interests of the city and the city's poor at heart and who appreciate all that New York City owes to its sick poor.

It would seem, then, that the history of Bellevue is really about to open up one of its most important eras under this new régime and as an amelioration of conditions has been sadly needed for many years it must be a source of congratulation to every one interested in New York City and especially its ailing poor that the greatest city of the western hemisphere is about to supply itself worthily with accommodations for those of its citizens who have no other resource but to throw themselves on the public bounty in the midst of their illness. When it is considered with what a handicap the medical and surgical staffs have

done their charitable work in the recent past and how much of their labor they have seen go in vain because of the unsuitable surroundings the crying need for quarters of our great metropolis of the West will be realized.

The plans for the new buildings of Bellevue Hospital, a brief description of which is here appended, have been made public by Dr. John Winters Brannan, President of the Bellevue Board of Trustees, in an address to the students of Columbia University on Friday, April 22. The preliminary work of the architects, McKim, Meade & White, in drafting, represented a single outlay of $75,000, and the construction calls for an expenditure of $15,000,000.

This magnificent building, of which it is hoped the city of New York will approve, is designed to occupy three full city blocks, from Twenty-sixth to Twenty-ninth streets, and First avenue to the East River. The extra land alone will cost $1,000,000 and a conservative estimate of the total cost of the institution is $14,000,000. It will be the largest, handsomest, and most completely equipped hospital in the world, and will accommodate some 2,500 patients. Quarters are to be provided for over 100 physicians.

The building material is to be Harvard brick, with light stone trimmings. In the center will be a dome, 100 feet in diameter and 200 feet in height, which may be utilized to provide apartments for some of the resident staff. It will be surmounted by stone pillars supporting a bronze figure.

In addition to the city property to be purchased, the total structure will require two additional acres to be acquired by changing the bulkheads along the water front. The board of trustees of the hospital has permission from the War Department at Washington to make this change and the Street Cleaning Department would aid in filling in the space. The driving of piles would be an expensive item. The building is to be H shaped and, from the prospectus that has been prepared by the architects, is not, in general outline, unlike the Capitol in Washington.

The main part of the building will be 150 feet or more back from the river, and the wings running out on each side will form a large court.

Of course, it is not expected that there will be a demand on the hospital's full capacity as soon as it is built. On the contrary, it is expected that the new institution will meet the demands made by the city's growing population for a considerable time, and, besides, it will, it is said, be possible, with the present plans, to add four more pavilions when they are needed.

It would also be possible to leave off two pavilions of the thirteen that are contemplated in the present plans and still accommodate 2,000 patients. Under such circumstances the building would probably cost between $8,000,000 and $9,000,000.

The long arms of the building running east and west from the main part will front on Twenty-sixth and Twenty-ninth streets. The thirteen pavilions will all be under one roof, but between them will be covered arcades to allow a free circulation of air. Only four of the pavilions will face on First Avenue, and they will be used for the alcoholic, insane and other psychopathic patients, leaving to the others the benefit of the view and the air on the river.

Architects' Elevation of the New Bellevue Hospital Building.—View from the East River.

The appearance of the hospital from the river and from First avenue, where the main entrance will be, will be practically identical, except that, owing to the slope toward the river, the building will be one story higher on that side. It will be seven stories high on the river side. It will be 715 feet from east to west and 712 feet from north to south.

With the exception of the dome over the main part of the building and the curved roofs over four of the pavilions, which the architects, it is said, have added to accentuate the pavilions and lend architectural support to the dome, all the roofs are flat.

Roof gardens will be used by convalescent patients, who will be carried directly to the roof in seven elevators. These roof gardens will have temporary wards accommodating 100 patients. The roof will be surrounded by a four-foot parapet.

In the front, as well as in the rear of the hospital, there will be grass plots 300 by 500 feet, on which additional pavilions may be added if necessary.

The administration building, which will contain all the executive offices and libraries of the hospital and will provide quarters for 100 male nurses in the lower portion of which patients will be taken at night to receiving wards, accommodating 100, on the ground floor in the center of the long south wing.

The five upper floors of the south wing will contain the medical wards. The limit of each ward will be twenty-five patients, but several rooms will be connected with each, and may be filled with beds if necessary. The service rooms connected with every ward will be complete and modern in equipment.

A pavilion which will be near the present entrance to the hospital will have the three lower floors given over to the ambulance department and carriage house. The upper part will contain the medical amphitheatre, with accommodations for 200 students.

The west part of the long north wing will have quarters for 350 male employees on the three lower floors, while the upper floors will be devoted to the pathological department. Further east on the ground floor will be the kitchen, storerooms, and the boiler room.

The five upper floors of the north wing will contain the surgical wards. The surgical amphitheatre will be equipped with ten small operating rooms, all within easy access of the various wards and complete in every detail.

The hydropathic department, designed to surpass that of any public, or, probably, even private institution, and to contain bathrooms for both employees and patients, will be on the ground floor of the central pavilion. It will be equipped with all modern apparatus for the treatment of disease by water, and will be one of the most remarkable new features of the hospital.

There will also be an elaborate system of balconies on all sides of the hospital. Each of the ninety-two wards will have either an open or an enclosed balcony of sufficient size to accommodate all the patients in each ward at one time.

Architects' Elevation of the New Bellevue Hospital Building.—View from the West side.

Besides the approval of the board of trustees of Bellevue and Allied Hospitals and the Board of Estimate and Apportionment, it is not altogether improbable that the plans for the new hospital will have to be passed on by the State Board of Charities before they are accepted.

This board will probably request the trustees to submit their plans for approval.

The Bellevue trustees have contended that the city charter and the statutes required them to submit plans for the buildings under their jurisdiction to the Board of Charities merely "for advice," which they could follow or not, and not for "approval."

The plans of the new Bellevue Hospital were drawn by Messrs. McKim, Mead & White, to whom we are indebted for the illustrations and specifications of the new building.

THE DIASTOLIC MURMUR IN DIAGNOSIS.*

BY AUSTIN W. HOLLIS, M.D.,
OF NEW YORK;
VISITING PHYSICIAN ST. LUKE'S HOSPITAL; CHIEF OF THE OUT-PATIENT DEPARTMENT; ATTENDING PHYSICIAN AT THE NEW YORK DISPENSARY.

THE study of the diastolic murmur presents more difficulties than are met with in the systolic variety. In its usual form it is simple and clear and its mere time and quality reveal the diagnosis in an instant, but no murmur can be more elusive in its site and intensity, while the possibilities of its characters are so numerous that they defy description as well as diagnosis. Eight varieties may be recognized.

The causes are aortic and pulmonary insufficiency, persistent ductus arteriosus, aneurisms, mitral stenosis, cardiorespiratory influences, pericardial, pleuropericardial.

1. *Aortic Insufficiency.*—In about 90 per cent. of the cases, the quality of the murmur is almost constant, being blowing and diminuendo. It follows the first sound after a slight pause and occupies the rest of the diastolic period, so that if the heart's action is not frequent the murmur is one of remarkably long duration. In the other 10 per cent. of the cases it may be rough, musical, rumbling, crescendo or of short duration, and may occupy any portion of the diastole.

The intensity varies greatly, in most cases it is marked, but no murmur can be more difficult to hear in slight cases or when compensation is failing.

The site of the murmur is not a fixed one in every case, in this feature it is unique. It may be heard localized at any point over the anatomical outline of the heart, but as a rule it has a point of maximum intensity from which it is transmitted downward toward the apex or to some extent upward along the great vessels or in any direction in proportion to its intensity. It is not often heard in the back unless the subject is thin and the murmur very loud, when it may be found between the inner border of the scapula and the spinal column. The points of maximum intensity in order of frequency are: just to the left of the base of the ensiform cartilage, over the second or third right spaces, over the third left space, in both instances near the sternum, and at the apex.

The cause of the varying point of maximum intensity is of great interest. When the murmur has its point of maximum intensity over the aortic area it is undoubtedly due to vibration of the aortic ring, but when it is elsewhere it must be caused by the impinging regurgitant stream producing vibration in that part of the wall of the ventricle where it strikes, but because of the mechanical differences at the point of the leak the direction of the regurgitant stream is not constant.

The diastolic bruit which may be heard over the great vessels by slightly compressing them with the stethoscope called Duroziez's sign, said to be a valuable sign of aortic insufficiency, is often hard to get, is not always constant and may sometimes be heard in anemia or marked dicrotism. I cannot consider it as more than an interesting curiosity.

A musical quality is not uncommon, in some instances a musical murmur can be heard across the room with the naked ear. This quality of sound is almost always produced at the aortic orifice by the vibration of a sharp edge of tissue, and in such cases it has its point of maximum intensity over the aortic area and is transmitted widely in all directions, especially downward. A musical murmur which recurs with some degree of regularity, say every few beats, is caused by a shifting stirrup of tissue which hangs from the center or edge of a diseased valve. When a musical murmur is localized at some other point than the aortic area it is due to the regurgitant stream producing vibration in a false band or chordæ tendineæ in the ventricle itself.

Roughness of quality is always due to conditions of the aortic orifice, and the murmur in such cases has its point of maximum intensity over the aoritc area, except in the so-called "Austin Flint murmur," which is localized at the apex and will be considered later.

Uniformity of intensity is uncommon, such murmurs are usually heard between the apex and end of the sternum. They have the swing of systolic murmurs and are often mistaken for such.

Shortness.—When a murmur is short and occupies an unusual period of the diastolic pause, one should always suspect some other cause than true organic aortic incompetency. In the cases which I have seen the cause has been due to a relative insufficiency from aneurisms, exceedingly great arterial pressure, or imperfect valvular coaptation from senile degeneration and anemia; the murmur being produced during the height of the arterial pressure and ceasing as it diminishes. Such murmurs vary with the arterial pressure and force of the heart's action, they come and go so that we may be led to think that we have confused an intense impure aortic sound with a murmur, but actually the murmur was present and disappeared. Murmurs which are short and occupy an unusual point of the diastolic period are almost always cardiorespiratory, but these will be considered later.

2. *Pulmonary Insufficiency.*—The diastolic lesion produced by this affection is much more constant in its quality and site than that of aortic insufficiency. Its maximum intensity is always just to the left of the sternum in the second or third spaces, it is transmitted by the wall of the right ventricle and unless intense is not heard at the apex. Its quality is usually more harsh and rumbling than the murmur of aortic insufficiency, and follows the first sound or systolic murmur which accompanies it more immediately in most cases and often seems like a continuation of the latter. The rumbling vibratory character is due

* Read before the St. Luke's Alumni Society, Dec. 11, 1903.

to the less rigid pulmonary ring and the lower tension of the lesser circulation. Pulmonary murmurs may be soft and blowing, but a musical quality is exceedingly rare.

3. *Persistent Ductus Arteriosus.*—A diastolic murmur from this cause is very infrequent. It resembles that of pulmonary insufficiency in quality and site, but it is usually shorter and more continuous with the systolic; this condition may be distinguished in some cases from pulmonary stenosis and insufficiency by less cyanosis, less clubbing of the fingers, a small right ventricle, and the more frequent presence of an accentuated pulmonary sound.

4. *Aneurismal Diastolic Murmurs.*—These are of two kinds; the first and most important is due to an actual aortic insufficiency, either relative, from stretching of the aortic ring or from implication of the valves in a degenerate process. In the majority of cases such murmurs have no distinguishing features in quality or position from the ordinary murmurs of aortic insufficiency, but in some instances the wall of the aneurism transmits the murmur to a much greater distance, especially to the right, while its quality may be more roaring, churning, or foundry-like.

The second variety of diastolic murmur caused by aneurism is quite uncommon; it is produced by the blood being forced out of a distended aneurismal sac through its narrow opening during the diastole. The point of maximum intensity is variable and depends on the situation of the aneurismal sac, it may be transmitted by the blood current or along the wall of the aneurism, it is a short murmur, and the intensity varies, depending on the force of the blood current and the size of the aneurismal cavity. Other signs of aneurism are usually present and are necessary for a correct diagnosis.

5. *Mitral Stenosis.*—In this condition three varieties of the diastolic murmur may be found. The most common and important is the so-called presystolic, of all murmurs this is one of the most unchangeable in its site and quality. Its maximum intensity is always at the apex, it is usually localized, but may be heard in some cases a short distance on either side of the apex. It is rough, rumbling and crescendo, running into the first sound which is short, high pitched and intense. The cause of this short intense first sound has been thought to be due to the small amount of blood in the left ventricle and the consequent ease with which it can empty itself, but this would hardly explain the sound in aortic insufficiency with a Flint murmur. I believe the most probable explanation is, that the coarse vibrations at the auriculoventricular septum stimulates the ventricle to a sudden contraction by irritation of the nervomuscular mechanism of the heart.

The duration of the presystolic murmur is variable, often it is a mere suggestion of a presystolic sound, but the first sound is always sharp if the murmur is present. While the presystolic murmur is generally due to mitral stenosis, it may be caused by aortic insufficiency. Such cases were first described by Austin Flint. The most likely manner in which the sound is made is by the forcing back of the mitral valves by the regurgitant aortic stream, an artificial stenosis being thus produced and the opposing auricular stream causing vibration of the mitral valves and a violent eddy. Why this effect is not always produced probably depends on the direction of the regurgitant aortic stream, and the state of tone or dilatation of the left ventricle, which may prevent it from being fully emptied during systole, thus allowing the regurgitant stream to lift the mitral valves. When a Flint murmur is present it is almost invariably accompanied by the regular diastolic murmur of aortic insufficiency, but in exceptional cases it is found alone. To distinguish this murmur from that of true mitral stenosis one must depend entirely on the character of the pulse, the size of the right and left heart, the intensity of the second sounds, and to some extent on evidences of pulmonary congestion and the history of the onset and cause of the disease. It is often impossible to make a correct diagnosis.

The second murmur, due to mitral stenosis, is long and somewhat rumbling or blowing, and occupies most of the diastolic period. The first sound may not be short and snappy. The murmur is heard between the apex and end of the sternum, and can only be differentiated from the murmur of aortic insufficiency by other signs.

The third murmur, due to mitral insufficiency, is heard just inside the apex and sometimes near the end of the sternum. It is very short, soft, and blowing, and occupies the first part of the diastole. It is due to the pent-up blood in the left auricle flowing swiftly into the left ventricle at the beginning of diastole, when the pressure in the ventricle is negative; the ordinary presystolic murmur is almost invariably present in these cases.

6. *Cardiorespiratory Influences.*—Murmurs may be produced in the lung tissue adjacent to the heart by the sudden change in the size of that organ which aspirates or expresses the air. Such phenomena are more common when the play of the lungs has been restricted by pleuritic adhesions.

Systolic cardiorespiratory murmurs are quite frequent and have often been described, but the diastolic have received very little attention, although they are by no means uncommon. They are frequently mistaken for organic murmurs, and such errors are serious when made by insurance examiners, or by the family physician. During the past year I have seen two men rejected by insurance examiners, and a young man who had been forbidden athletic sports for three years by his medical advisor on account of the presence of this murmur. They may be found anywhere along the anatomical border of the heart, occasionally under the clavicle on either side, more commonly the left, their most frequent sites are just above and inside the apex or in the fourth space just to the right of the sternum. I have never heard a diastolic cardiorespiratory murmur posteriorly, although the systolic is not uncom-

mon there. They are fairly well localized, more so than the systolic, but if intense they may be transmitted some distance. They occupy a portion of the diastolic period, but what portion is not fixed. As a rule it is heard immediately after the systole. The quality is fairly constant, either soft and blowing, or puffing. The intensity varies with respiration; there is always a certain period in the respiratory cycle when the murmur is at its greatest intensity, and another when it can scarcely be heard or is wholly inaudible. At its point of greatest intensity, if the breath is held the murmur is constant and uniform. In some cases the respiratory influence is very slight, even producing no greater change than may be caused by respiration on ordinary organic murmurs. These cases are very difficult of diagnosis, but the short duration of the murmur, its early occurrence and soft, puffy quality, together with the absence of organic signs, should make the diagnosis clear, but if the heart is enlarged, the pulse full and quick, and the second aortic sound accentuated, the problem may be exceedingly difficult or impossible to solve on the first examination.

7. *Pericardial.*—When pericarditis is present, both systolic and diastolic murmurs are heard at some time during its course, their time of occurrence alone distinguishing them. The quality is superficial, rubbing or grazing, soft or harsh. The intensity varies, often being loud and harsh, or very soft, but as a rule it is of medium intensity. Pressure with the stethoscope may intensify the murmur. The duration is generally shorter than that of endocardial murmurs, and the sound may be broken, making two short murmurs. It follows the first sound or murmur almost immediately, giving a to and fro quality. Its site at the beginning and toward the end of the disease is most frequently in the third and fourth spaces, just to the left of the sternum, but may be heard in severe cases quite widely to the right and left of the sternum, and as high as the first rib. It is not transmitted far. A very soft murmur may be difficult of diagnosis; on account of the faint apical impulse, massive cardiac dulness, especially upward, and feebleness of the first sound, which is often more intense upward over the third or fourth spaces, its pericardial nature may be determined.

8. *Pleuropericardial.*—This murmur differs from the former in only four main particulars; the site is always at or a little above and inside of the apex; respiration has a decided influence, for at some period of the cycle the murmur may disappear or become fainter, and there is always some point during the respiratory cycle when, if the breath is held, the murmur is best appreciated; other signs of pericarditis are absent; indications of dry pleurisy are almost always present.

The cases which I present illustrate some of the difficulties which I have set forth in this incomplete description of the diastolic murmur.

Case I.—Male; thirty-six years old; driver. His general health has always been good. No rheumatic history. He had a chancre eight years ago, no positive secondary symptoms. He came under my care a few weeks ago for pains in the right shoulder and the side of the chest. The cause of these was rather vague and did not improve under salicylates or potassium iodide. There were no other complaints. On physical examination nothing was found but a very slightly enlarged heart, and a very soft diastolic murmur in the fifth space just to the left of the sternum, which on some days was impossible to hear. The pulse was about ninety, somewhat larger and quicker than normal. It alone would give no clue to the diagnosis. I mention this patient to illustrate the ease with which such a case can be overlooked, as many of my best fourth-year students have examined him, but no one has made the diagnosis of aortic insufficiency.

Case II.—Male; housesmith; twenty-eight years old. He has a marked history of inflammatory rheumatism. Four years ago he was in St. Luke's Hospital for several weeks with an attack of acute articular rheumatism, and endocarditis with marked embarrassment of the heart action. This was not his first attack. He came to the out-patient department very soon after he left the hospital. The physical signs then were about the same as they are now. The heart is greatly enlarged in all directions, a loud diastolic murmur of a blowing quality is heard over the aortic area and is transmitted to the apex. At the apex a very loud systolic transmitted to the axilla is heard. The point of special interest is a localized, high-pitched, musical murmur in the third and fourth spaces close to the sternum. I believe that the musical sound is made in the ventricle through the vibration of a band. The case is also of interest because the man has been able to do hard work for three years.

Case III.—Male; thirty-two years old; porter. He has been under my care for some years at the New York Dispensary, attending irregularly, and usually appearing after a drunken spree. There is no rheumatic history. He had syphilis twelve years ago. He presents a very typical appearance of aortic insufficiency, throbbing vessels, big left heart, loud diastolic murmur with maximum intensity over the pulmonary area. The chief interest lies in a presystolic murmur at the apex which is a good example of the so-called Austin Flint murmur. The pulse, absence of a large right heart, and syphilitic origin rule out mitral stenosis.

Case IV.—Male; thirty-five years old; janitor. He has had no rheumatic or syphilitic history. He has had a chronic nephritis with considerable albumin for an unknown time. The heart is very slightly enlarged. In the second space just to the right of the sternum there is a visible and somewhat palpable pulsation, over which there is a moderate dulness. A diastolic murmur is heard over it and is transmitted toward the apex. The pulse is not quick or large, undoubtedly being influenced by the increased arterial tension and the presence of a small aneurism at the sinus of Val-

salva, but the murmur itself is due to an actual insufficiency of the implicated aortic valves.

Case V.—Male; thirty-seven years old; plasterer. He has always been strong and well, except for myalgic pains, which brought him to the dispensary. He has a moderately enlarged heart, and a strong pulse. Above and inside the apex there is a short diastolic murmur which is heard over a small area, its intensity is not uniform, but varies with respiration. Because of the pulse and character of the murmur it is undoubtedly an example of the cardiorespiratory variety.

Case VI.—Male; twenty-six years old; cutter. He came to the New York Dispensary a year ago for the same symptom of which he now complains, that is, dyspnea on exertion. He made two calls then and has not consulted a physician until last week, when he returned with the same difficulty. The physical signs show that the apex beat is one inch to the left of normal and rather diffuse, but not forcible. The right heart is apparently not enlarged, although it is impossible to determine a moderate enlargement by percussion. At the apex there is a very distinct, soft purring thrill and presystolic murmur, the first sound at the apex is short and sharp, but the second sound can be distinctly heard as well. Over the base the second sounds are of equal intensity. The pulse is large, soft and rather quick, about 80 to the minute, at the angle of the jaw a very distinct throbbing is visible. It would be impossible to regard this case as one of mitral stenosis, but although the symptoms and signs, except for the murmur, point to aortic insufficiency, one hesitates to make that diagnosis without the usual diastolic murmur.

Since presenting this case a soft diastolic murmur has appeared at the end of the sternum.

111 West Forty-seventh Street.

THE INFLUENCE OF BOVINE TUBERCULOSIS ON HUMAN HEALTH.*

BY MAZYCK P. RAVENEL, M.D.,

OF PHILADELPHIA;

BACTERIOLOGIST OF THE STATE LIVE STOCK SANITARY BOARD OF PENNSYLVANIA; ASSISTANT MEDICAL DIRECTOR OF THE HENRY PHIPPS INSTITUTE FOR THE STUDY, TREATMENT AND PREVENTION OF TUBERCULOSIS.

Had your invitation to speak on this subject come to me in the year of the London Congress on Tuberculosis, I would have been obliged to have depended largely on theoretical considerations to defend my position, although even at that time I had collected a certain amount of evidence which convinced me of the correctness of my belief in the essential unity of tuberculosis as seen in man and in cattle, and in the intercommunicability of the disease between these two species of mammalia. Some of this evidence was presented at that Congress. The stand taken by Koch at that time had the effect of stimulating research in practically every part of the world, so that to-day we are in possession of facts that seem to me to be irrefutable. I will therefore confine myself as nearly as possible to well established facts, and to the conclusions which they justify.

Study of Tubercle Bacilli.—Study of cultures of the tubercle bacillus isolated from various types of tuberculosis in man and in animals has not yet shown differences which enable us readily to determine the origin of a given culture. The most marked and constant difference is the greater pathogenic power shown by the bovine bacillus for all experimental animals which have been used, with the possible exception of swine, which in my experience have proved so very susceptible to both races that it is hard to draw a distinction between them. Koch, however, includes swine among the animals which show a much greater susceptibility to bovine cultures than to those from human sources. The list of animals for which this greater susceptibility has been shown is a long one, including horses, cows, asses, goats, sheep, dogs, cats, rabbits, guinea-pigs, and our nearest relative, the monkey. The result is the same by every method of inoculation tried. It would then be a most remarkable and anomalous circumstance for man, who is one of the most susceptible of all animals to be immune, or even strongly resistant, to the most virulent race of tubercle bacillus yet discovered. It has most certainly not been shown that man possesses this immunity, and no one has been able to discover any special means of defense in the human body against the bovine tubercle bacillus. Until this is done we are bound to believe that, in common with all other mammalia, he shares this susceptibility to its ravages.

Variation of Virulence.—While it has been shown conclusively that a greater pathogenic power is the most marked distinguishing characteristic between the bovine and the human bacillus even this is not constant. You will recall, however, that Koch in 1901, held that this difference in virulence gave us a sure method of diagnosis between the two races. If the culture had power to cause general infection in cattle it was then certainly of bovine origin, while failure to do this proved it to be human. Replying to this, Prof. McFadyean said, "If a low degree of virulence for cattle is to be taken as the distinguishing feature of human bacilli there will be no difficulty in proving that the human disease is sometimes transmitted to the lower animals."

Confirmation of this has recently come from the Tuberculosis Commission appointed by the Imperial Sanitary Office of Germany. Kossel, in his preliminary report says that among seven cultures examined by them, four of which were isolated from cattle and three from swine, one was found which caused only infiltration at the point of inoculation, with some caseous foci in the related prescapular gland, and in one mediastinal, but without the generalization usually seen following inoculations of bovine bacilli. He concludes that "among bovine tubercle bacilli

* Read before the New York Academy of Medicine, Section on Pediatrics, April 7, 1904.

there can also occur differences with regard to virulence."

Koch and his followers are very active in making discoveries which have been known elsewhere for a long time.

Pathogenic action of the bovine tubercle bacillus for man.—Accidental inoculations in the laboratory and in post-mortem work on cattle have given us some opportunity of observing the effects of the bovine tubercle bacillus on man. I have reported four such cases, all of which resulted in the formation of typical lesions which required excision before healing took place. In two of these cases the bacillus was isolated and studied, excluding the possibility of infection from human sources. In one instance the recovered organism was compared with the original culture. A number of similar cases are on record. A common feature of all of them is their resistance to treatment, final cure resulting only after radical excision. In a case recently reported by Troje, which seems to be free from the objection usually raised, the disease extended up the arm and two years after the original infection had involved the glands of the axilla and sub-clavicular space. In a few instances general infection and death is reported to have followed these accidental inoculations, but the evidence is not entirely conclusive. A careful study of these wound infections, and comparison with similar infections with human tuberculous material, shows (1) that the bovine bacillus grows well in the human body under the most unfavorable circumstances producing typical lesions, and (2) that it shows for man at least as great pathogenic power as the human bacillus under identical circumstances. As the skin is known to be the most unfavorable tissue for the tubercle bacillus, we are justified in holding that organs and tissues which are known to be favorable soil for the growth of the human bacillus will prove equally favorable for the bovine organism.

Clinical Observations.—Clinical studies have not given us a great deal of aid in the solution of the question before us. We have, however, some 38 cases on record in which the evidence is very strong and convincing. All of them are open to the same criticism, as it is plain that all other sources of infection have not been excluded with certainty. This objection will always apply to clinical observations to a greater or less extent, but I do not consider that it is fair to exclude them on this account. With respect to other diseases such as typhoid fever, diphtheria and scarlet fever, we constantly accept without question evidence which is not nearly so strong as that we are asked to reject when tuberculosis is concerned. Much of the evidence on which the general belief in the respiratory invasion of tuberculosis rests is lamentably weak. If we question the accuracy of those cases in which death has followed accidental inoculation, or those other cases where milk from tuberculous cows appears to have been the cause of the disease, for the reason that all other sources of infection have not been excluded, we should apply the same strict methods of examination to those cases in which infection appears to have taken place through the respiratory tract and by exposure to the human disease. This has not generally been done. In our clinics and hospitals it is the rule to question the patient as to his or her family history, and if the answers show exposure to another case of phthisis, the source of infection is considered as demonstrated. No effort is made to exclude the use of tuberculous meat and milk, even if it were possible to get reliable data concerning these points. In this way has the great mass of our statistics concerning infection in tuberculosis been collected. The belief generally held that dried and pulverized sputum is the general infecting material is theory pure and simple. It is supported by very little experimental evidence, and no exact clinical evidence that I am aware of. Do not understand me to say that I disbelieve these teachings, for I do not; but I protest that Koch and those who follow him in disregarding the importance of bovine tuberculosis in relation to the human disease set up a standard of accuracy for their scientific opponents which they do not honor themselves.

Primary Intestinal Tuberculosis.—Those who doubt that tuberculous food products play any considerable part in the causation of human tuberculosis base their opinion mainly on the alleged rarity of primary intestinal tuberculosis. Koch says "that a case of tuberculosis has been caused by ailments can be assumed with certainty only when the intestine suffers first, *i.e.*, when a so-called primary tuberculosis of the intestine is found." It requires but little thought to see how misleading this statement is. It leaves out of consideration infection through the tonsils and upper digestive tract, and recent experimental work proves that no such dogmatic statement can be made.

Passage of Tubercle Bacillus Through Healthy Intestine.—As long ago as 1890, Dobroklonski working under Cornil, showed that the tubercle bacillus can penetrate the wall of the intestine of some animals without causing any demonstrable lesion, and that it does not require long to do so.

The late Prof. Nocard observed that if he drew blood from horses at certain periods of digestion, the serum would become contaminated even if divided into small lots of 100 c.c. On the other hand, if the bleeding was done during fasting, the serum could be preserved in liter flasks without loss. In seeking an explanation of this phenomenon, two of his students, Desoubry and Porcher, found that the chyle of dogs fed with soup containing considerable fat showed many colonies of bacteria when plated. When a plain bouillon without grease was given the chyle was free from bacteria. Nicolas and Descos have shown that practically the same thing holds true for the tubercle bacillus when ingested with fat. During the winter of 1902-1903, I have made similar experiments at the laboratory of the State

Live Stock Sanitary Board of Pennsylvania. The method was as follows: After keeping a dog under observation for some days to make sure that it was healthy, a purge of castor oil was given in order to rid the intestine of any substance which might injure the mucous membrane mechanically. At the end of this time a single meal consisting of equal parts of warm water and melted butter made into an emulsion, in which tubercle bacilli were stirred, was given. The dog was killed after three and one-half to four hours, during active digestion, and as much chyle as possible collected, together with the mesenteric glands. With this material guinea-pigs were inoculated. In 8 out of 10 dogs it was found that tubercle bacilli had passed through the intestinal wall, and from the extent of the lesions found in the guinea-pigs I feel justified in saying that the bacilli had penetrated in large numbers. In every case the entire intestinal tract of the dogs was carefully examined, and in two microscopic sections were made from several portions of the gut. In no case was any lesion found. These experiments prove that tubercle bacilli can easily penetrate healthy mucous membrane without leaving any trace of their path.

When we remember how directly the chyle passes up the thoracic duct and is thrown into the venous circulation near the heart, from which it passes immediately to the lungs, it does not seem unreasonable to claim that an infection through the intestine may first show itself in the lung, or, at least, that the lesion in the lung will be so nearly contemporaneous with that of the intestine that it will be impossible to say which is primary.

I have here the intestines and lungs of two monkeys which were infected by feeding with pure cultures of tubercle bacillus in a series of experiments on the comparative virulence of the human and bovine organisms. In both the lungs are extensively diseased. We were unable to find any lesion whatever in the intestine of one, and in the other (A45007) there was only a slight lesion, with caseation of three glands in relation to the upper portion of the tract. In this animal there was, however, enlargement and caseation of the cervical lymph glands, pointing to invasion through the tonsils or pharynx.

If these two specimens were shown without history most pathologists would pronounce them cases of respiratory infection, yet they were kept under conditions which precluded this possibility, and were tested with tuberculin before the experiment began. May not these experiments explain many of those numerous cases seen in children in which pathologists are unable to decide the mode of invasion? In the series of autopsies reported by Northrup in 34 out of 125 cases he could not determine the portal of entry.

Post-mortem Statistics.—I will not go into the consideration of post-mortem statistics, because I understand they are to be treated in another paper this evening. The figures concerning the primary lesion are not at all uniform. In England only have we anything like uniformity in the findings, which show a considerable percentage of primary intestinal tuberculosis for that country. It must be remembered that a single positive result is worth more than many negative ones, and it is impossible to explain away the figures given by such men as Carr, Guthrie, Shennan and Still.

Infection Through the Tonsils.—The numerous observations made of late years leave no doubt that the tonsils sometimes act as the port of entry for the tubercle bacillus. As well put by Baup, "discussion is only possible as to the greater or less frequency of these lesions, and their pathological importance," a position sustained not only by the work of other observers but by his own, in which he examined the tonsils from those cases only in which tuberculosis of the lungs was absent and other ports of entry could be excluded. Dieulafoy, by the inoculation of guinea-pigs, found tuberculosis in 15 of 96 cases. Latham, who was careful to employ only the interior portions of the tonsils, in 45 consecutive cases of children from three months to thirteen years of age, seen at autopsy, found seven which were tuberculous. One of the most recent studies of this subject is that of Friedmann, who examined the tonsils obtained from 91 children at autopsy, and 54 cases removed by operation, all but one of the latter under five years of age. Of the 91 cases, in three there was tuberculosis, probably not primary; in five there was tuberculosis, probably primary, with secondary involvement of lymphatic glands, intestine, and bone; in one the tonsils showed many tubercles, giant cells, and tubercle bacilli, the rest of the body being free; in seven (two with and five without tuberculosis in other parts of the body) the tonsils contained typical giant cells, but no bacilli could be demonstrated; in three giant cells attributed to other causes were found; in eleven, which showed extensive tuberculosis of other parts of the body, the tonsils were free, but showed scars; in four the tonsils were free, there being tuberculosis of the internal organs; in three bacilli were demonstrated in smear preparations, though no tubercles were found. In the remaining 54 cases tuberculosis was not found in any part of the body. Only one of the operative cases showed primary tuberculosis.

Friedmann concludes that tuberculosis of the tonsils is quite common in children, and that the infection takes place directly from food, and not through the lymph, blood, or by inhalation. In swine and in cattle infection through the upper digestive tract is very common.

Many corroborative facts could be added, but enough has been said to show the fallacy of looking exclusively in the intestine for evidence of infection by food. The lymph channels leading from the upper digestive tract empty into the large veins near the heart, so it is not hard to understand how tubercle bacilli which may penetrate the tissues in this region soon find their way to the lung. In illustration of what I have

said, I show here photographs of the tonsils and lungs of a pig infected by feeding a pure culture of tubercle bacillus. This animal was one of four, two of which were fed human and two bovine bacilli. All of them contracted general tuberculosis, most marked in the lungs, and ending in death. Three of the four showed lesions like those shown, but in only one could any injury of the intestine be found.

Isolation of Bovine Tubercle Bacilli from Human Lesions.—The most direct and positive proof that bovine tuberculosis is responsible for a certain amount of tuberculosis in man is given by the finding of the bovine bacillus in human lesions. With this object in view I began in 1900 to look for cases of intestinal tuberculosis in children as those most likely to be caused by the bovine bacillus. In June, 1901, I succeeded in isolating from the mesenteric glands of a child sent to me by Dr. Alfred Hand from the Children's Hospital in Philadelphia a culture which has been designated BB. This culture showed a most intense virulence for cattle, killing two calves in seventeen and twenty-seven days respectively, and a six year old cow in seventeen days. Excepting in the first generation when some irregularity of staining was noticed, this culture has always shown every characteristic of the bovine tubercle bacillus, and must be regarded as having come directly from cattle. I have since isolated two other cultures from mesenteric glands of children which have unusual virulence. Culture U was considered an ordinary human culture until it was used in some feeding experiments on dogs, when it showed such unexpected virulence that I inoculated a calf with it. The animal was killed after forty-six days, as it was moribund. The autopsy showed a general infection.

Recently I have obtained another culture which lies between BB and U, and which I consider bovine. It produces general infection and death in rabbits on subcutaneous inoculation, and killed a calf weighing 255 pounds in thirty-five days. The late Dr. De Schweinitz isolated the tubercle bacillus twice from intestinal lesions in children, and Dr. Theobald Smith has found it once in such cases. In Europe Fibiger and Jensen report having found it three times, and Kossel speaking for the German Tuberculosis Commission, tells us that out of 16 children examined, four proved to have been infected by the bovine tubercle bacillus. Two of these four cases are described as "miliary tuberculosis," one starting from a bronchial adenopathy, and the other from a mesenteric adenopathy. The remaining two were intestinal tuberculosis. It appears from this that even those cases which show the primary lesion in the bronchial glands, and which are considered to be so certainly of respiratory origin, may be caused by the bovine tubercle bacillus.

When a Commission which is evidently doing its best to sustain Koch has to acknowledge that 25 per cent. of the children examined by it show lesions due to the bovine tubercle bacillus it seems time to abandon the doctrine that tuberculosis of cattle has little or no effect on human health.

It appears to me that the case might well rest on the positive evidence afforded already by the discovery of the bovine germ in children.

Frequency of Bovine Infection.—I will not attempt to say what proportion of children die of bovine infection. If I have sustained my contention that the two diseases are essentially the same and intercommunicable, it is evident that the number of children in any given locality who become infected from bovine sources will vary directly with the prevalence of tuberculosis in the cattle of that district, and with the extent to which unsterilized milk is used as food.

In order to determine the percentage of children who derive their infection from cattle it would be necessary to isolate from a large number of those who died from tuberculosis the offending organism, and to determine its origin. The cost of this is prohibitive for private laboratories, and it must be undertaken at the public expense if done at all. The findings already published are too few in number to form the basis of an estimate, but they show conclusively that it is not a rare occurrence to find the bovine tubercle bacillus in the lesions of children. The German Commission found it in four out of 16 cases examined; De Schweinitz twice in four cases; Theobald Smith once in five cases, and at the laboratory of the State Live Stock Sanitary Board I have found it in two out of five cases. Febiger and Jensen have found it in three instances.

Extent of Tuberculosis in Cattle.—I will not weary you with an array of statistics showing the prevalence of bovine tuberculosis. It is well known to be a scourge, and to be especially prevalent in milch cows of the herds on the dairy farms near large cities,—at least this has been the case in the past, to a great extent. The introduction of certified milk has had a widespread educational effect, and has done much to better the condition of many herds, directly as well as indirectly.

I hold strongly to the opinion that it is not only the cow with tuberculosis of the udder that is dangerous, though this is no doubt an especially perilous condition. Dilution with the milk of healthy cows undoubtedly lessens the infectiousness of such milk but cannot make it safe. Dr. Theobald Smith showed in 1893 that the tubercle bacillus could be found in the milk of tuberculous cows, when the udder was free from disease, so far as the naked eye could tell. In a series of experiments with the mixed milk of five cows which reacted to tuberculin, but were in good physical condition, I found it infectious for 15.8 per cent. of the guinea-pigs inoculated. No attempt was made to concentrate the bacilli; on the contrary, the whole quantity of the milk was well shaken in order to imitate natural conditions. No lesion of the udders could be found during life or after death of the cows.

Rabinowitsch and Kempner found that 10 out

of 15 cows, which reacted to tuberculin but showed no evidence of udder disease, gave milk containing tubercle bacilli. They conclude that "milk may contain tubercle bacilli; first, in beginning tuberculosis, without discoverable disease of the udder; and, second, in latent tuberculosis that can be detected only by the tuberculin reaction;" also, "milk from cows that react to tuberculin must be suspected of being infectious in every case."

Conclusion.—At the present time the weight of the available evidence is in favor of the view that the chief source of infection in children, as well as in adults, is the human tubercle bacillus, and that the portal of entry is the respiratory tract. It has, however, been proven conclusively that the bovine tubercle bacillus is responsible for a certain proportion of the deaths from tuberculosis in children, and there is strong evidence at hand to show that the number of children infected from bovine sources is quite large. Whether the number be large or small, it is none the less our duty to guard against the use of milk from tuberculous cattle for food.

CLINICAL ASPECT OF CHRONIC MYOCARDITIS.*

BY JOHN W. BELL, M.D.,
OF MINNEAPOLIS, MINN.;
PROFESSOR OF PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE, UNIVERSITY OF MINNESOTA.

CLINICALLY, the ills which befall the heart may be divided into two broad classes: (1) Those due to pathologic changes in the valves, causing deformity and impaired function, and later, secondary changes in the heart muscle, and (2) those due to pathologic changes in the myocardium, causing cardiac insufficiency accompanied by enlargement. Clinically, structural disease of the heart means either deformed valves or weakened walls, leading sooner or later in either case to cardiac insufficiency with all its attendant evils.

Unfortunately, in the past, our text-books have given but little space to the consideration of chronic myocarditis, hence it is an imperfectly understood and much overlooked condition.

It is not my purpose in this brief paper to discuss the pathology or etiology of chronic myocarditis, except for the purpose of rendering more clear the clinical aspect of the subject.

Pathology.—Much diversity of opinion and confusion exist as to the pathologic changes present in chronic myocarditis. In this paper the term chronic myocarditis is used in its broadest sense to include any morbid changes which manifest themselves clinically in the weakened myocardium, the result largely of fibroid or fatty changes in persons at or beyond midlife, previously free from valvular disease. The microscope reveals a variety of pathologic metamorphoses, pointing as a rule to fibroid or fatty changes in the heart muscle, either circumscribed or diffuse in character.

Chronic interstitial myocarditis may and not infrequently does represent a later reparative stage of acute myocarditis, but more often it is secondary to conditions interfering with the nutrition of the heart, such as gradual narrowing of the coronary arteries or their branches, the result of endarteritis, atheroma, arterial fibrosis, or the more sudden and complete occlusion of the vessel by an embolus or thrombus. Localized changes, fibroid or fatty in character, are most frequently found in the walls of the left ventricle, posteriorly, toward the apex, causing local weakness and thinning, with pouching of the myocardium, aneurismal in character.

Etiology.—Males suffer from myocardial weakness much more frequently than females. The pathological changes in the myocardium are of slow and progressive development, the result of long continued injurious influences. These injurious influences, which fret and embarrass the heart, may come from within or without the organism, or, in some cases, there may be a union of both. My observation leads me to believe that the long-continued, even moderate use of alcohol, especially when associated with the use of tobacco, is one of the most potent factors in the causation of chronic myocarditis as we meet with it in American men. It is astonishing how promptly alcohol and tobacco aided by strong coffee (two or three times daily) will disturb the cardiac rhythm of the active, nervous, susceptible man of affairs. In susceptible persons disturbance of cardiac rhythm and rate, associated with an irritable condition of the heart, is noticeable soon after the tobacco habit is formed; in the less susceptible its injurious effects are delayed until midlife or beyond, and are observable in the form of more pronounced disturbance of rhythm, rate and force, associated with palpitation and precordial discomfort.

Tobacco, by increasing the rate and disturbing the rhythm, thereby increasing the labor as well as perhaps interfering with the perfect nutrition of the heart muscle, leads gradually to a degenerative change, and alcohol acts even more promptly in producing sclerotic changes.

Gout or the gouty diathesis, by paving the way for early stiffening of the arteries, including changes in the coronary arteries, is often visible in the background as a causative factor.

Syphilis, like gout, is often responsible for myocardial disease, especially fibroid changes. Among the more frequent causes may be enumerated coronary disease, general arterial fibrosis, chronic renal disease, endo- and pericarditis, anemia, phosphorus, etc.

Symptoms.—The rational symptoms of myocardial insufficiency, at first are usually vague and inconstant; not alone is this true of a series of cases, but of the same case at different times. Death may occur suddenly without evidence of symptoms or physical signs. Breathlessness, amounting to dyspnea on exertion, is one of the earliest and most constant symptoms. Slight vertigo, headache, precordial distress, palpitation

* Read before the St. Louis County Medical Society.

and later attacks of angina are among the more common symptoms. The pulse becomes irregular in rate, rhythm and force; perchance intermittent. Slight overwork or worry precipitates an attack of palpitation. Later dyspnea becomes more pronounced and constant, with attacks of severe cardiac asthma, especially at night. In other cases the breathing, waking or sleeping, is of the Cheyne-Stokes type, often accompanied by pulmonary congestion, edema, and later, hydrothorax; the latter often before evidence of fluid is noticeable elsewhere. In still other cases precordial pain occurs and later attacks of true angina, especially if extensive coronary disease is present. In other cases, especially of fatty heart, the patient may manifest muscular twitchings, pseudo-apoplectic attacks, with transient hemiplegia.

Without wearying you longer with a recital of symptoms, I feel sure you are all familiar with the following clinical picture: An active business man of sedentary habits, a free user of tobacco, a daily, moderate user of alcohol, and a generous liver, begins to suffer from breathlessness on the slightest extra exertion, also from precordial discomfort at intervals, especially if effort follows a full meal. Excitement, overwork or worry precipitates palpitation; he becomes painfully conscious of the presence of a heart; consults his physician who finds a pulse, usually irregular in rate, rhythm, force or tension, often intermittent. A physical examination of the heart and vessels reveals a weak, diffused impulse in the nipple line; arteries unchanged or slightly stiff. On careful percussion the deep cardiac dulness is found slightly increased. On auscultation the heart sounds may be practically normal, but as a rule the first sound is short and feeble, with variable accentuation of aortic second sound.

Unless the true condition is promptly recognized and counteracted by judicious treatment, we see the shortness of breath, precordial discomfort and other symptoms of myocardial weakness increase from month to month, gradually removing the once active man of affairs from his sphere of usefulness.

Diagnosis.—Chronic myocarditis gives rise to no pathognomonic signs, consequently in the early detection of the disease much depends on the judgment and experience of the clinician. He should keep constantly before him the fact that the vast majority of persons who begin to manifest signs of cardiovascular disease after midlife suffer from myocardial disease, rather than valvular. In the beginning of every suspected case of myocardial disease a complete history should be taken, especially as to age, family tendencies, habits and previous diseases. The urine should be carefully investigated for evidence of renal disease. The diagnosis is based largely on the history, age, state of the vessels, and symptoms, rather than on evidence of physical changes in the heart. In the majority of cases we must be content with a diagnosis of myocardial insufficiency; as to the exact nature of the myocardial changes present in a given case we can only speculate.

Treatment.—For the purpose of treatment we divide the clinical course of the disease into two periods or stages: (1) The period of progressive and often slow development of myocardial weakness, accompanied by breathlessness, precordial distress, irregular pulse, and occasional attacks of palpitation, and (2) the period of advanced myocardial weakness, accompanied by symptoms of pronounced cardiac insufficiency, such as constant precordial distress, dyspnea, cardiac asthma, Cheyne-Stokes breathing, frequent attacks of palpitation, marked irregularity of pulse, angina, tachycardia, bradycardia, Stokes-Adams quartet of symptoms, and later all the symptoms of general engorgement.

Each individual case must be carefully studied as regards the existence of any constitutional vice, the exact state of the heart and arteries, the character of the pulse, and the digestive powers. Having then a clear conception of the patient's condition it should be carefully and frankly explained to him, unless there be some special reason to the contrary, when it should be explained to a friend or relative.

If called to treat a case in the first period or stage our initial endeavor should be to discover and remove every possible cause of cardiac irritation and embarrassment. Our second endeavor should be to so regulate the diet, exercise and habits of the individual as to bring the general nutrition as well as that of the heart muscle up to the highest point and there maintain it. For this purpose, in addition to hygienic and dietetic measures, general tonic treatment, consisting, according to indications, of strychnine, arsenic and iron is indicated. The question of exercise must be carefully considered in relation to each individual case, and with special reference to the condition of the myocardium. In early cases the pathological changes are not far advanced, especially in obese persons, where fatty infiltration, rather than degeneration, is the rule, graduated exercise is especially beneficial.

However, in the large majority of cases of chronic myocarditis absolute rest in the recumbent position will be found necessary for a few weeks at least. The patient's habits should be carefully regulated; tobacco, alcohol, coffee and tea should be interdicted. He should be urged to lead a quiet, orderly and temperate life, as free from worry and excitement as is compatible with our modern civilization. The diet must be adapted to the digestive powers and the wants of the system. All rich, bulky foods, especially those inclined to induce flatulence, should be excluded. The patient should be advised to sleep and eat regularly, eating three meals daily, composed of concentrated, non-fermentative, nutritious food, suited to the requirements of his special case; the midday meal should always be the principal one; no solid food between meals; little or no fluid with meals. Patients should be

urged to sleep at least ten hours out of every twenty-four, with a midday rest of at least one or two hours following the midday meal, in order to minimize the daily labor of the heart; the latter injunction should be rigidly followed during the remainder of the patient's life. In dealing with this condition it is attention to such little things as relate to eating drinking and doing which makes success possible.

In order to intelligently advise and treat an individual suffering from chronic myocarditis, we must inquire carefully into his heredity as well as his past and present condition, also have clearly in mind the etiological factors responsible for the varied pathological changes present in chronic myocarditis. The fat, flabby man of sedentary habits suffering from fatty infiltration of the heart must, of necessity, receive different advice and treatment from that indicated in the thin, spare, ill-nourished individual. In the management of myocardial insufficiency we rely largely on rest, graduated exercise, massage, resisted movements, saline carbonated baths, tonics and saline cathartics. In suitable cases saline baths of a proper temperature aid very materially in restoring myocardial tone.

Before instituting a course of baths, advanced arterial fibrosis and aneurism must be excluded, also advanced cardiac insufficiency with dropsy. It is well to begin with a bath of ten minutes duration, which should consist of fifty gallons of water at a temperature of 98° F. gradually lowered to 94° F. The water should contain one per cent. of sodium chloride and one-tenth per cent. of calcium chloride. The temperature of the second bath is gradually lowered to 90° F.; thereafter all baths should be given at that temperature. The percentage of chlorides should be gradually increased, sodium three per cent. and calcium one per cent. and the bath prolonged to twenty minutes. As a rule, carbonic acid should be added by the tenth day. The baths, if beneficial, should render the pulse slower, fuller and more regular; should improve the character of the impulse, and should decrease the area of deep cardiac dulness.

The course of baths should extend over a period of five or six weeks, omitting it every fourth day. The principle underlying the baths is that the percentage of salines be increased, temperature lowered and duration lengthened. I consider it safer, and equally beneficial, to follow the plan suggested above of gradually lowering the temperature of the water during the first few times until the patient becomes accustomed to the cool bath.

Unfortunately, these patients do not present themselves for treatment until pronounced weakening of the myocardium, as shown by marked venous and visceral congestion has occurred, indicating the second or advanced stage of the disease.

We are then confronted with the problem of medicating a weak and degenerated heart muscle in an individual having, in the majority of cases by virtue of his age, suffered certain vascular, as well as extravascular changes, causing increased intra-arterial and cardiac blood pressure. In advanced cases absolute rest in bed must be enjoined, for a variable period, the length of time depending entirely on the indications present in that particular case. The question of the amount of rest indicated or required in a given case of myocardial insufficiency, demands the most careful consideration on the part of the physician in order to avert disaster.

The treatment of advanced cases of myocardial insufficiency, associated with pronounced venous and visceral engorgement, with evidence of beginning anasarca, is wholly palliative, directed to the relief of symptoms and associated complications. For the reduction of the more or less constant high arterial tension present in many cases we rely mainly on the iodides and nitrites. I have found iodide of sodium, in from three to five grain doses, three or four times daily, the most satisfactory agent in dilating the arterioles, thus reducing intra-arterial pressure; the action of the iodides is much more prolonged than that of the nitrites, hence the iodides are to be preferred.

Strychnine, digitalis, strophanthus, sparteine and caffeine render most excellent service in giving tone to the weakened heart muscle, when combined with a vasodilator like soda iodide, nitroglycerin, erythol or sodium nitrite. I desire to emphasize the value of long-continued, very small doses of digitalis, combined with a vasodilator, in myocardial disease associated with arterial fibrosis or chronic renal disease. In case the stomach is irritable, the urine scanty and the arterial tension low, it may be given by the rectum with good results. The morning saline, preferably magnesia sulphate, given one hour before breakfast, aided by an occasional bedtime dose of calomel, adds much to the comfort of the patient and aids greatly in delaying the evil presence of pronounced venous engorgement and anasarca.

In case angina pectoris occurs, the attack should be promptly met by the inhalation of amyl nitrite and the subcutaneous use of morphine and nitroglycerin. In view of the intense suffering associated with angina, the attendant should instruct the nurse, in case of an attack, to immediately administer a generous subcutaneous dose of morphine and nitroglycerin.

In the management of pronounced myocardial insufficiency, with its attendant evils, no method of medication has proved so satisfactory in my hands as that of subcutaneous medication, assisted by rest, massage, baths and saline cathartics. Our resources are sorely tried, in the treatment of this disease—a veritable struggle with mortality, often extending over a period of years—for it should be constantly borne in mind that we are dealing with an incurable condition.

In conclusion, I desire to emphasize the necessity for prompt recognition of the early symptoms of myocardial weakness, believing that no practitioner is justified in ignoring or passing over

as unworthy of therapeutic attention the breathlessness, precordial distress and irregular pulse so frequently encountered after midlife.

ACUTE APPENDICITIS AND ITS MEDICAL TREATMENT.*

BY G. N. BEST, M.D.,
OF ROSEMONT, N. J.

BY way of introduction it may be said that this paper is prepared from the standpoint of the general practitioner, or, to be more exact, from the standpoint of the country doctor; and if any excuse is needed for selecting so trite a subject for your consideration, it may be found in the fact that there are but few diseases he is called upon to treat that give him greater anxiety and more "worriment" than does acute appendicitis.

The reasons for this are obvious. In the first place, this disease is a variable one, and sometimes as treacherous as it is variable; its constitutional manifestations do not always indicate the gravity of the local affection and a case that appears to be progressing favorably for the first few days may, in an incredibly short time, present a condition quite the reverse of favorable. The diagnosis, moreover, is not always as easy as it is sometimes claimed to be. Not a little difficulty may be experienced in differentiating it from such diseases as cholecystitis, enterocolitis, intestinal obstruction, renal and biliary calculo, typhoid fever; in the female, from diseases of the uterus and its appendages, notably pyosalpinx and extra-uterine pregnancy and in the child from pleurisy and pneumonia. Spellissy[1] reports 190 cases with lesions of 20 varieties of structure and 68 species of lesion, all mistakenly considered to be of appendiceal origin.

In the second place, it may be stated that the numerous articles bearing on this disease, that have from time to time appeared in various medical journals and in reports of medical societies, instead of furnishing a trustworthy guide to its treatment, often embarrass and confuse the physician by a medley of diverging, not to say contradictory, opinions. While it is true that a number of the leading surgeons, both in this country and in Europe, especially such as are engaged in abdominal work, have declared with considerable unanimity that acute appendicitis is always a surgical disease from start to finish, and that to treat it medically is not only useless but wellnigh criminal; yet the rank and file of the profession have been slow to accept these teachings, inasmuch as they seemed too radical for general practice, not to mention the fact that at times they had a distinct commercialistic clang, which probably made them less acceptable than they would otherwise have been. But I have no hesitation in saying that as a general rule, to which there may be exceptions, it is easier for the physician and safer for his patient to have the appendix removed in the earlier stages of the disease than it is to trust to medical treatment. It would probably be still safer to have the appendix removed before it became diseased—if, indeed, there was such a time in the history of an individual—and I sometimes think that, while the surgeon is at work the removal in the male of both internal and external appendices might contribute not a little to the solution of certain social and economic problems now bearing heavily on the human family.

If operative measures were always feasible or permissible, in the cases under consideration, little more would need be said, but as they are not, and this is the plea I wish to be distinctly understood as making, I see no reason why their medical treatment should not be considered as we would that of any other disease. The assertion sometimes made that such treatment is not only useless, but even worse, is probably the outcome of a hysterical temperament subjected to undue pressure and not worthy the attention of serious-minded people.

Before proceeding farther in this discussion, it may be well to state what is to be understood by operative measures not being feasible or permissible. They are not permissible in those cases in which, after the attending physician has explained to his patient and to the immediate family the nature of the attack and that the chances for recovery are better with an operation than without, there is a direct refusal to allow it, usually coupled with the statement that Mr. Blank had appendicitis as badly as any one could have it and got well without an operation, and if *he* did, why should not I? The inference is plain: if the patient does not recover, it is the doctor's fault. While it is true that such cases are not so common as they were formerly, since operations have become fashionable and therefore more easily endured, yet I think that every practitioner of wide experience will confirm the statement that even now they are not altogether rare.

Again, if there is not a direct refusal, there is often a conditional assent, which amounts to the same thing, the patient reserving to himself the right to wait and see whether he is going to die or get well before he decides for or against an operation. It may be said that the objections to operative measures are simply a matter of prejudice, possibly of ignorance, twins as they usually are, and that it is the duty of the physician to remove them by the subtle art of persuasion. *Tempus fugit.*

It is, however, in country practice, in the sparsely settled rural districts, away from hospitals, away from competent surgeons and trained nurses, where railroads and telegraphs are few and far between, that we meet with cases in which operative measures are not feasible and where to carry out the surgical dictum To operate! To operate at once! is simply impossible. If the case in hand is a light one, removal to a

* Read before the Lehigh Valley Medical Association, Allentown, Pa., January 28, 1904.

hospital might aggravate it, and if grave, the patient is too ill to warrant the undertaking. The home environments, moreover, of many of these cases are not favorable to the after-treatment of a serious surgical operation. Another consideration which tends to complicate matters not a little: the physician not infrequently sees his patient for the first time some two or three days after the beginning of the disease.

Again, the medical man himself may be handicapped by certain conditions which make it questionable whether he will be in a position to render his patient the proper attention if he is subjected to an operation. It may be in midwinter when the roads are blocked with snow, or in early spring when they are impassable with mud, Obstetrical cases on the outer confines of his "bailiwick" may keep him on the ragged edge of expectancy a day or two at a time, several miles away from his patient. This is no fancy sketch, I assure you, but one that may be duplicated time and again by any one engaged in country practice. These people have bodies, I am quite sure, and souls, I am told, and when they are sick they must be attended to. If the treatment they receive is not the best that medical and surgical science can offer it is probably the best the conditions will allow.

A few words as regards the etiology and pathology of acute appendicitis. It has been but a few years since the younger surgeons, many of whom are now full-fledged, with a world-wide reputation, responding to an invitation to address a country society and selecting for their subject the disease under consideration, deemed it proper to carry with them a pocket full of foreign bodies, ranging in size from a grape seed to a tenpenny nail, to impress on their hearers the relation betweeen cause and effect. Now, it is thought that a true foreign body in the sense of its introduction from without and not of formation within the organism is but rarely the immediate cause of appendicitis. Concretions and fecal matter sometimes found in the appendix, are to be regarded as the result of a diseased condition of this organ, rather than the cause of it. *A subacute catarrhal condition of the intestinal canal* is probably at the bottom of many, if not most, cases. Boardman Reed[2] says it is "the duty of the medical man to prevent the occurrence of acute attacks of appendicitis. Often a long time before its actual outbreak there are symptoms that point to the gathering storm. There is constipation with intervals of diarrhea. There is often persistent and increasing anemia. In the urine there are signs of disturbed intestinal digestion. There is often obstinate gastric disturbance and especially increased acidity of the stomach. This gives rise to a catarrhal irritation of the intestines which also involves the appendix. If these symptoms are relieved before they terminate in pathological changes the appendicitis may be prevented." Frederick Treves[3] says that "in women the outbreak of appendicitis is often coincident with the menstrual period," and Deaver[4] that "the appendix is more liable to destructive inflammation because it is an organ now in the course of disappearance"—an assertion more easily made than proved. Dieulafoy[5] and Golouboff[6] consider acute appendicitis an infectious disease, and Lucas-Champonniére contends that it possesses an epidemic character. Dieulafoy goes so far as to call it a *maladie toxi-infecticuse;* and the more closely it is studied the stronger this view appears. In certain cases of a fulminant type the symptoms point to a toxemia, in some of which an operation within forty-eight hours will disclose a blackened appendix, cecum, and spots of the same character on the ileum and sometimes on the colon; this condition necessitating extensive resections of the intestinal canal.[7]

As in other infectious diseases, the poison may be so virulent, or the individual so susceptible to its influence, one or both, as to overwhelm the system from the onset, thus preventing the normal evolution of the disease and making the diagnosis extremely difficult, if not impossible. What particular germ of the intestinal flora is responsible for the toxins in question is not known to a certainty. Both the streptococcus and the colon bacillus have been accused of being the active agents. Suspicion, however, falls the more heavily on the former, and it is quite possible that when these germs are shut up in a diseased appendix the peculiar environments enable them to develop toxins which under more normal conditions would not appear; but, so far, this hypothesis is little more than a supposition and it remains for the pathologist to favor us with more exact data.

In this connection the observations of Simonin[8] are worthy of consideration. This author presented a series of 18 cases of general infection, severe scarlet fever, erysipelas, mumps and infectious angina, in which were observed positive signs of inflammation of the appendix.

"This organ," he says, "may be considered as a kind of tubular ganglion which takes part during the course of general infection in defense of the economy and receives the germs by the circulation of the blood as well as of the lymph. The first degree of inflammation of this organ, which might be called appendical folliculitis or adenitis, is shown by pain at the point of McBurney. This is also called latent catarrhal appendicitis. The second grade presents a peri-adenitis, that is to say, an inflammation of the cellular tissue around the appendix. The inflammatory reaction may propagate this as far as the mucosa and the peritoneum. Then follows a crisis or a colic of the appendix more or less acute, with distinct pain, nausea, vomiting and signs of peritonitis. Finally, an appendicitis with abscess may develop after perforation has occurred. The streptococcus is certainly the most frequent agent. Most of these appendicites arise from this germ. It is the same germ which is present ordinarily in angina, erysipelas, scarlatina, grip, measles, smallpox, and it may be the initial agent

of infection or associated with some other. Certain authors consider sclerosis of the appendix with obstruction, which one sees so often at autopsies, the result of several attacks of inflammation, latent, subacute or acute, which have occurred during infectious diseases. Such infectious diseases commonly occur during childhood."

If a fresh example were needed to show the limitations of human judgment, the conflicting views advanced from time to time as regards the proper treatment of acute appendicitis would furnish it. In this country most of the talking has been done by the class known as operators who have taken considerable pains to fly the red flag full in the face of their medical confrères; but present indications favor the hope that we have passed the crisis of indiscriminate operating and that we are now on a foundation in which more conservative and more judicious counsel will prevail. At the last meeting of the American Medical Association the surgical section unanimously "agreed that operation for appendicitis should be done the moment the condition was diagnosed, if the symptoms pointed to a limitation of the disease to the appendix itself. After involvement of the peri-appendicular structures the treatment of the case should be along the lines suggested by Ochsner, namely, frequent gastric lavage, absolutely no food or medicines by the mouth, rectal feeding unless it produces pain. Patients who had passed the primary involvement of the appendix, when subjected to this treatment recovered sufficiently to be operated on in 97 per cent. of cases, said operation being followed practically by no fatality."[9]

In his recent paper, read before the Medical Society of Kings County, Dennis says "that the pendulum has swung too far toward indiscriminate operation, but now the introduction of the interval operation has brought the pendulum back to swing within its proper limits."[10] A little more emphatic, but in the same line, are the remarks of an eminent professor of abdominal surgery in one of our medical colleges. In addressing his senior class he said, "Gentlemen, let me impress on you the fact that every case of appendicitis is not a surgical one. The professional cutter who wants to slash every patient who has a pain in his right iliac fossa is a dangerous animal to run at large in any community. Surgery is the noblest of professions, but the basest of trades. Nothing can compensate for the want of skill; but the morbid desire to cut, with no conscience to restrain, makes the doctor very unsafe, although a man of ability."[11]

It is not, however, within the scope of this paper to discuss the surgical treatment of acute appendicitis except in a general way, and then for the light it may throw on the management of those cases in which operative measures are not feasible or permissible, at least during the acute attacks. Personally, I do not wish to be understood as being adverse to surgical interference. I make use of it in my own practice and am fully satisfied that by this means many lives have been saved. On the other hand, I am just as fully satisfied, although it may be difficult to make it so appear, especially to those who are inclined to think differently, that not a few have been lost which would have recovered without it. That this contention is not entirely without foundation is evident from the fact that Dennis, in the paper already cited, says that "the mortality of the simple operation (that is, for catarrhal cases) is appalling in the hands of an inexperienced surgeon. The writer has knowledge of one surgeon who operated on 19 consecutive cases with 19 deaths." Surely it could not be said this surgeon was without experience when he operated on his nineteenth case! Dennis goes on to say that "it would seem that surgery had reached its climax in regard to operation for appendicitis; yet the time will never come when there will be no death rate. Complications are certain to arise that are beyond the control of the surgeon." Until it can be shown that by surgical treatment there is no death rate, is it not ungracious indeed to send out in flaming headlines when some unfortunate has succumbed to this disease: "Another victim of the medical treatment of appendicitis!"? Is it not reasonable to suppose that the result might have been the same under surgical treatment?

Although no reliable statistics are available showing the mortality of this disease under medical treatment, taking one case with another as they occur in general practice, yet it may be fairly approximated at somewhere between 10 and 15 per cent. Ill[12] says that "while there is no doubt that nine out of ten cases of appendicitis may get well without operation, it is the tenth case we want to save"; and Dennis (*loc. cit.*) that "the mortality in appendicitis in all cases under medical treatment is about 16 per cent. . . . and the mortality under surgical treatment about 4 per cent." He fails to state, however, on what authority these assertions are made. Obviously hospital records ought to show the death rate under surgical treatment but not under medical. It is possible that the figures which this author gives are "bold approximations," for in speaking of the advantages of early operations, he cites Fowler, whose 127 cases operated on within forty-eight hours showed a mortality of 17 per cent., just 1 per cent. more than Dennis allows under medical treatment. The truth seems to be that surgical cases, taking them as they occur in a general hospital, show a death rate of somewhere between 5 and 12 per cent. These figures refer to the present time; formerly the percentage was much higher.

No less an authority than Deaver claims that "cured cases are illusory. There is always a focus left in which the tissues are less resistant. Subsequent attacks are almost sure to occur. No one, no matter what his experience, can foretell the course of appendicitis or how severe the next

attack will be. To permit pus formation without surgical intervention is almost a crime. The ordinary medical treatment for appendicitis is little better than high-grade Christian Science."[13]

While I am quite willing to acknowledge that I know but little about gradations in Christian Science, I do know that these cases get well, and what is more, I know they continue to be well, at least as far as the appendical trouble is concerned. Among many disadvantages, the country practitioner, in whose cases of acute appendicitis surgical treatment is often neither feasible nor permissible, has one advantage, namely, an opportunity to study the natural history of the disease. This is denied to his surgical brother, who imagines that every case must be operated on and that right speedily. The country practitioner learns by careful observation that these cases are not so fatal as they are made to appear, that in the vast majority they recover, and that, too, without the troublesome sequellæ of strictures and herniæ which not rarely make life not worth the living. And while it is true that no one can foretell with absolute certainty at the onset of an attack of appendicitis what the result will be, the same is equally true of many other diseases.

It is evident that no fast rules can be followed in the management of acute appendicitis. Much must be left to the individual judgment of the attending physician. In those simple cases, sometimes called irritative or catarrhal, but little medical treatment is needed during the immediate attack. A thorough evacuation of the bowels is of the utmost importance. For this purpose small and frequently repeated doses of calomel may be given with advantage, followed, if necessary, by a saline cathartic or a copious enema thrown well up into the bowels. If it does not offend the stomach, a large dose of castor oil answers the purpose most admirably. If pain is a prominent symptom, small doses of the deodorized tincture of opium are advisable with either hot or cold applications to the affected side. These attacks usually subside in from two to five days, during which time the patient should be kept in bed and allowed but little nourishment and that of the blandest kind. Since about 30 per cent. of these cases have more than one attack an interval operation should be carefully considered by the physician and his patient, who should be instructed not to allow his bowels to become constipated and to exercise discretion as regards his diet. The following mixture, which may be given continuously for two or three months or even longer, if desired, and in which the amount of cascara may be increased if it is found necessary, is to be recommended as a preventive measure.

℞ Sodii salicylatis (pure) ..... ʒij
Ext. Cascaræ sagradæ Fld. (P. D. & Co.) . ʒij
Ol. Menth. pip. ..... gtt. j
Aquæ puræ ..... ʒj
Syrupi ..... q.s. ad ʒviij
M. et sig.: Teaspoonful before each meal.

In cases in which pus formation occurs the attacks are more protracted and more severe. *An abscess is nature's method of curing a diseased appendix;* and while she may not always succeed, she does so more frequently than one would expect. Sir Frederick Treves, in commenting on the advisability of an operation after a first attack, says that "if there has been an abscess in the first attack then I think an operation may be put out of court altogether because that abscess will in certainly 95 per cent. of the cases obliterate the organ and render it harmless."[14] This statement agrees so perfectly with my own observations that I have not the least doubt of its correctness. Since an abscess, originating in inflamed and necrotic tissues in any part of the body, does not usually reach its full development under one week's time or sometimes even longer, we should not expect an appendiceal abscess to show well-marked improvement in a shorter period; but as long as the tenderness does not extend beyond the median line and a highly sensitive and clearly circumscribed tumor is manifest, a hopeful prognosis may be entertained if not always expressed. While it is possible for these abscesses to empty themselves into the peritoneal cavity or to point externally, or for the pus to work its way into the stomach or the bladder, such cases are exceptional. In the vast majority they discharge their contents directly into the intestinal canal and the patients speedily recover. It would not be difficult to cite a number of instances proving the accuracy of this observation.

As in the catarrhal form it is advisable to commence the medical treatment of these cases by brisk purgation, and I agree with Lucas-Championniere in deeming it desirable to keep the bowels open during the entire course of the disease. As pain is usually a prominent symptom, it should be combated by opium and hot poultices, the latter I think decidedly preferable to ice-bags, as they are undoubtedly more agreeable to the patient. It is not necessary to carry the narcotic to the point of stupefaction. I usually advise the occasional smearing of the sensitive area with ichthyol ointment and the internal administration of tablets of salol and phenacetin, one every four hours. If the disease takes on a well-marked septic form, with high fever and profuse sweating, as it sometimes does, quinine, with or without turpentine, is indicated. But little nourishment should be allowed and this of the most easily digested kind. Patients usually do best with as little as possible. The Ochsner treatment, the so-called "starvation treatment," may be admissible in hospital but, for obvious reasons, not in country practice.

Incidentally, it may be said that in those cases in which the abscess ruptures into the peritoneal cavity surgical interference is always indicated. While it is possible to recover under medical treatment they do so but rarely.

Lastly, we shall consider the disease in its fulminating form. Whether this form is a variety of

acute appendicitis or a distinct disease is an open question. As before stated, its symptomatology points to a profound toxemia. It is quite different from a general peritonitis, set up by the rupture of an abscess into the peritoneal cavity. Its course is more rapid; nausea and vomiting are well marked and continuous; the pulse is usually rapid and small, the temperature variable, rarely high, sometimes subnormal; facial expression exceedingly bad; no tumor is apparent and the right iliac fossa but slightly, if any, more sensitive than the left; pain is usually referred to the region about the umbilicus or to the epigastrium; the abdomen is distended and the bowels resist purgative measures; mental apathy or stupor, with intervals of great restlessness, is not infrequent. These are the cases that the surgeon does not see in time and the medical man entirely too soon for his comfort. Whether under surgical or medical treatment they usually terminate fatally, and that, too, within a week, not rarely at the end of two or three days.

SUMMARY OF AN EXPERIMENTAL RESEARCH INTO THE USE OF ALCOHOL, NITROGLYCERIN AND AMYL NITRATE IN SHOCK AND COLLAPSE, WITH ILLUSTRATIVE PROTOCOLS.

BY GEORGE CRILE, M.D.,

OF CLEVELAND, OHIO.

Alcohol.—In the experiments reported the immediate effect of intravenous administration was observed. The first effect usually noted was a decline in the blood pressure. In the majority of such instances a compensatory rise followed; in a number of instances no change in this respect was noted; in but few was there a rise in the blood pressure. The average length of the stroke of the manometer (height of pulse-wave) was increased. There was no evidence that the heart beat more forcibly. In animals reduced to varying degrees of surgical shock the usual effect of an average dose of alcohol was the production of a further depression; in smaller doses but little effect was noted, while in larger doses a more marked decline often occurred. In a few instances, in deep shock, the administration of a considerable dose was followed by almost immediate death. In a number of experiments with alcohol the decline in the blood pressure was as prompt and as marked as in the administration of the amyl nitrate and nitroglycerin. In no instance, in the normal animal, did death immediately follow the largest dose of alcohol, but the more profound the shock the more marked was the depressing effect of alcohol. In a number of experiments alcohol was given prior to procedures intended to produce shock, but it is not certain that it rendered the animal more susceptible, although it is quite certain that the susceptibility was not diminished.

Nitroglycerin and Amyl Nitrite.—The immediate effect of nitroglycerin and amyl nitrite upon the pulse was an increase in its volume and a decrease in frequency. The immediate effect upon the respiration varied. At times there was a slight increase, more frequently a slowing of respiration. The immediate effect upon the blood pressure in almost every instance was a fall. The decline was usually rapid. There were but few exceptions, and in these there was usually no effect. A rise in the blood pressure was rarely observed. In the latter it was but temporary and usually followed by a fall. The descent in the blood pressure was gradual and rather rapid, the ascent, more gradual. Compensation usually took place in a few minutes, the rising curve being more gradual than the falling. The portion of the curve representing the deepest part of the decline was rounded. Compensation in the majority of experiments was complete. In those experiments in which the later blood pressure was not equal to that before the administration of nitroglycerin it was usually lower. Each time the doses were repeated the effects were almost as marked as the preceding time, even when the repetitions were at short intervals. On administering repeated doses, each twice as large as the preceding one, the effects were proportionately increased. Most of the animals tolerated very large repeated doses; excessive doses produced convulsions and respiratory failure. The blood became darker before the animal died.

During the convulsions the blood-pressure rose and fell with the muscular spasms. In the experiments in which the animal was in deep shock and the blood pressure gradually falling, there was no evidence to show any decrease in the rapidity of the decline. On the contrary, as nearly as could be estimated, nitroglycerin distinctly increased the rapidity of the decline. The effect of nitrate of amyl was in every respect similar to that of nitroglycerin. In many instances the heart beat irregularly after the injection. On the whole, nitroglycerin and amyl nitrite increased shock.

Experiments.—Alcohol.

Dog 1, male mongrel: excellent condition; weight, sixteen kilos. Dog 2, female mongrel; excellent condition; weight fourteen kilos. Dog 3, male mongrel; excellent condition; weight, nine kilos. The tracheal and carotid canula were applied. Ether anesthesia.

At 12:05, dog 1, blood pressure, 140 mm.; stroke, 12 mm.; pulse, 140; respiration, 80. Dog 2, blood-pressure, 112 mm.; stroke, 13 mm.; pulse, 156; respiration, 80. Dog 3, blood-pressure 98

mm.; stroke, 18 mm.; pulse, 152; respiration, 10.

At 12:45, the animal was reduced to shock by skinning and irritating the denuded surfaces. Dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 144; respiration, 92. Dog 2, blood-pressure, 95 mm.; stroke, 18 mm.; pulse, 132; respiration, 76. Dog 3, blood-pressure, 50 mm.; stroke, 20 mm.; pulse, 128; respiration, 52. In dogs 1 and 2 the sciatics were electrically stimulated. A sharp fall was recorded, followed by a gradual rise. In dog 3 a sharp rise and fall, with a gradual return to the former level, was noted.

At 12:50, dog 1, blood-pressure, 125 mm.; stroke, 10 mm.; pulse, 132; respiration, 88. Dog 2, blood-pressure, 80 mm.; stroke, 18 mm.; pulse, 132; respiration, 72. Dog 3, blood-pressure, 70 mm.; stroke, 16 mm.; pulse, 132; respiration, 56.

From 12:51 to 12:53 an injection of 22 minims of whisky was administered. An increasing pulse rate, slower respiration and a rise in the blood-pressure in each animal followed.

At 12:54, dog 1, blood-pressure, 130 mm.; stroke, 16 mm.; pulse, 148; respiration, 68. Dog 2, blood-pressure, 75 mm.; stroke, 18 mm.; pulse, 160; respiration, 60. Dog 3, blood-pressure, 70 mm.; stroke, 18.; pulse, 148; respiration, 48.

At 12:55, the sciatics were stimulated, with results similar to the previous stimulation.

At 1:02, dog 1, blood-pressure, 110 mm.; stroke, 12 mm.; pulse, 148; respiration, 76. Dog 2, blood-pressure, 75 mm.; stroke, 19 mm.; pulse, 144; respiration, 56. Dog 3, blood-pressure, 80 mm.; stroke, 16 mm.; pulse, 144; respiration, 48.

At 1:02-30, dog 1, an injection of 22 minims of whisky was administered.

At 1:02-30, dog 2, an injection of 22 minims of whisky was administered.

At 1:03-45, dog 3, an injection of 22 minims of whisky was administered.

At 1:05, dog 1, blood-pressure, 115 mm.; stroke, 12 mm.; pulse, 148; respiration, 64. Dog 2, blood-pressure, 70 mm.; stroke, 20 mm.; pulse, 168; respiration, 52. Dog 3, blood-pressure, 80 mm.; stroke, 16 mm.; pulse, 152; respiration, 44.

At 1:08, the sciatics were electrically stimulated; the results were as before.

At 1:13, dog 1, blood-pressure, 112 mm.; stroke, 10 mm.; pulse, 144; respiration, 80. Dog 2, blood-pressure, 70 mm.; stroke, 12 mm.; pulse, 152; respiration, 52. Dog 3, blood-pressure, 75 mm.; stroke, 13 mm.; pulse, 132; respiration, 48. An injection of 22 minims of whisky was administered in dogs 1, 2 and 3. The results were as follows: Dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 144; respiration, 68. Dog 2, blood-pressure, 68 mm.; stroke, 10 mm.; pulse, 152; respiration, 52. Dog 3, blood-pressure, 80 mm.; stroke, 13 mm.; pulse, 132; respiration, 44.

At 1:38, dog 1, blood-pressure, 118 mm.; stroke, 10 mm.; pulse, 150; respiration, 60. Dog 2, blood-pressure, 60 mm.; stroke, 11 mm.; pulse, 156; respiration, 64. Dog 3, blood-pressure, 74 mm.; stroke, 17 mm.; pulse, 152; respiration, 48.

At 1:38-15, dog 1, an injection of 22 minims of whisky was administered.

At 1:38-30, dog 2, an injection of 22 minims of whisky was administered.

At 1:39, dog 3, an injection of 22 minims of whisky was administered.

At 1:41, dog 1, blood-pressure, 115 mm.; stroke, 11 mm.; pulse, 144; respiration, 68. Dog 2, blood-pressure, 60 mm.; stroke, 8 mm.; pulse, 156; respiration, 52. Dog 3, blood-pressure, 70 mm.; stroke, 16 mm.; pulse, 112; respiration, 144.

At 1:43, electrical stimulation of the sciatics was made with former results.

At 1:52-30, dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 156; respiration, 64. Dog 2, blood-pressure, 70 mm.; stroke, 8 mm.; pulse, 156; respiration, 52. Dog 3, blood-pressure, 55 mm.; stroke, 16 mm.; pulse, 96; respiration, 40.

At 1:53-15, dog 1, an injection of 22 minims of whisky was administered.

At 1:54, dog 2, an injection of 22 minims of whisky was administered.

At 1:55, dog 3, an injection of 22 minims of whisky was administered.

At 1:56, dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 160; respiration, 68. Dog 2, blood pressure, 70 mm.; stroke, 8 mm.; pulse, 156; respiration, 56. Dog 3, blood-pressure, 60 mm.; stroke, 10 mm.; pulse, 96; respiration, 40.

At 1:58, the sciatics were electrically stimulated. The results were not so marked as formerly.

At 2:05, dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 152; respiration, 68. Dog 2, blood-pressure, 75 mm.; stroke, 10 mm.; pulse, 142; respiration, 52. Dog 3, blood-pressure, 35 mm.; stroke, 18 mm.; pulse, 108; respiration, 36. Dog 1, an injection of 22 minims of whisky was given.

At 2:05-30, dog 2, an injection of 22 minims of whisky was given.

At 2:06-30, dog 3, an injection of 22 minims of whisky was given.

At 2:08, dog 1, blood-pressure, 118 mm.; pulse, 156; respiration, 56. Dog 2, blood-pressure, 78 mm.; stroke, 10 mm.; pulse, 152; respiration, 52. Dog 3, blood-pressure, 55 mm.; stroke, 16 mm.; pulse, 96; respiration, 36.

At 2:19, dog 1, blood-pressure, 11 mm.; stroke, 8 mm.; pulse, 160; respiration, 56. Dog 2, blood-pressure, 88 mm.; stroke, 19 mm.; pulse, 156; respiration, 44. Dog 3, blood-pressure, 55 mm.; stroke, 14 mm.; pulse, 100; respiration, 36.

At 2:19-30, dog 1, an injection of 22 minims of whisky was given.

At 2:20, dog 2, an injection of 22 minims of whisky was given.

At 2:21, dog 3, an injection of 22 minims of whisky was given.

At 2:22, dog 1, blood-pressure, 118 mm.; stroke, 10 mm.; pulse, 160; respiration, 72. Dog 2, blood-pressure, 84 mm.; stroke, 9 mm.; pulse, 148; respiration, 56. Dog 3, blood-pressure, 60 mm.; stroke, 16 mm.; pulse, 60; respiration, 36.

At 3:02, dog 1, blood-pressure, 100 mm.; stroke, 8 mm.; pulse, 60; respiration, 70. Dog 2, blood-pressure, 70 mm.; stroke, 8 mm.; pulse,

150; respiration, 52. Dog 3, blood-pressure, 55 mm.; stroke, 16 mm.; pulse, 56; respiration, 40.

At 3:55-15, an injection of 22 minims of whisky was administered to dogs 1, 2 and 3.

At 3:56, dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 160; respiration, 68. Dog 2, blood-pressure, 70 mm.; stroke, 8 mm.; pulse, 156; respiration, 56. Dog 3, blood-pressure, 60 mm.; stroke, 10 mm.; pulse, 56; respiration, 40.

At 3:58, electrical stimulation was applied to the sciatic nerve. Not so active a vasomotor mechanism was observed as in previous stimulations.

At 4:05, dog 1, blood-pressure, 115 mm.; stroke, 10 mm.; pulse, 152; respiration, 68. Dog, 2, blood-pressure, 75 mm.; stroke, 10 mm.; pulse, 142; respiration, 52. Dog 3, blood-pressure, 55 mm.; stroke, 18 mm.; pulse, 100; respiration, 36.

At 4:06, an injection of 22 minims of whisky was administered to dogs 1, 2 and 3.

At 4:08, dog 1, blood-pressure, 118 mm.; stroke, 11 mm.; pulse, 156; respiration, 56. Dog 2, blood-pressure, 78 mm.; stroke, 10 mm.; pulse, 152; respiration, 52. Dog 3, blood-pressure, 58 mm.; stroke, 9 mm.; pulse, 100; respiration, 36.

At 4:19, dog 1, blood-pressure, 111 mm.; stroke, 8 mm.; pulse, 160; respiration, 56. Dog 2, blood-pressure, 88 mm.; stroke, 9 mm.; pulse, 156; respiration 44. Dog 3, blood-pressure, 55 mm.; stroke, 14 mm.; pulse, 100; respiration, 36.

At 4:20 an injection of 22 minims of whisky was given to dogs 1, 2 and 3.

At 4:22, dog 1, blood-pressure, 118 mm.; stroke, 10 mm.; pulse, 160; respiration, 72. Dog 2, blood-pressure, 84 mm.; stroke, 9 mm.; pulse, 148; respiration, 56. Dog 3, blood-pressure, 55 mm.; stroke, 12 mm.; pulse, 132; respiration, 40.

At 4:48-15, dog 1, blood-pressure, 114, mm.; stroke, 8 mm.; pulse, 156; respiration, 64. Dog 3, blood-pressure, 60 mm.; stroke, 12 mm.; pulse, 128; respiration, 40.

At 4.49-45, an injection of 22 minims of whisky was administered to dogs 1, 2 and 3.

At 4:50-45, dog 1, blood-pressure, 121 mm.; stroke, 8 mm.; pulse 172; respiration, 68. Dog 2, blood-pressure, 75 mm.; stroke, 7 mm.; pulse, 144; respiration, 52. Dog 3, blood-pressure, 60 mm.; stroke, 11 mm.; pulse, 120; respiration, 44.

At 4:52, the sciatics were stimulated. The results were as in the last observation.

At 5:03, dog 1, blood-pressure, 120 mm.; stroke, 9 mm.; pulse, 144; respiration, 68. Dog 2, blood-pressure, 75 mm.; stroke, 9 mm.; pulse, 144, respiration, 52. Dog 3, blood-pressure, 62 mm.; stroke, 11 mm.; pulse, 120; respiration, 44.

At 5:04, an injection of 22 minims of whisky was administered to dogs 1, 2 and 3.

At 5:07, dog 1, blood-pressure, 130 mm.; stroke, 11 mm.; pulse, 168; respiration, 48. Dog 2, blood-pressure, 74 mm.; stroke, 8 mm.; pulse, 148; respiration, 48. Dog 3, blood-pressure, 65 mm.; stroke, 10 mm.; pulse, 96; respiration, 36.

At 5:26-30, dog 1, blood-pressure, 120 mm.; stroke, 8 mm.; pulse, 160; respiration, 66. Dog 2, blood-pressure, 80 mm.; stroke, 10 mm.; pulse, 152; respiration, 56. Dog 3, blood-pressure, 65 mm.; stroke, 8 mm.; pulse, 100; respiration, 40.

At 5:27-30, an injection of 22 minims of whisky was administered to dogs 1, 2 and 3.

At 5:30, dog 1, blood-pressure, 123 mm.; stroke, 10 mm.; pulse, 153; respiration, 72. Dog 2, blood-pressure, 74 mm.; stroke, 10 mm.; pulse, 132; respiration, 56. Dog 3, blood-pressure, 70 mm.; stroke, 8 mm.; pulse, 88; respiration, 40.

At 5:31, electrical stimulation was applied to the sciatics. The usual effect was noted.

At 5:35, the animals were killed with intravenous injections of MgSO.

Experiment. Nitroglycerin.—Small mongrel pup; weight, three kilos. Morphine and ether anesthesia. At 12:05, blood-pressure, 120 mm.; pulse, 210; respiration, 60.

At 12:06-30, an intravenous injection of 10 minims of a one per cent. solution of nitroglycerin was made. At 12:07, blood-pressure, 60 mm.; pulse, 192; respiration, 48. At 12:10, blood-pressure, 110 mm.; pulse, 210; respiration, 48. At 12:15, blood-pressure, 100 mm.; pulse, 180; respiration, 36. The animal was then killed.

MEDICAL PROGRESS.

SURGERY.

Experimental Surgery on the Vasa Deferentia.—Animal experiments for the purpose of determining the permeability of the canal when total or partial resection of the epididymis had been done, and the vas sutured either to the testicle or the resected epididymis, have been made by W. Bogoljuboff (Archiv f. klin. Chir., Vol. 72, No. 3). He operated on various animals, horse, dogs, sheep and cats, and claims that, in several instances, the anastomosis formed between the vas and the epididymis permitted the passage of the spermatozoa. It seems that the most suitable locality for making the anastomosis is between the vas and the head or the upper half of the epididymis. In most cases an intermediate space is formed which includes at the ends the canals of both structures. The author suggests that the operation may be applied clinically in certain cases where inflammatory conditions of the epididymis have produced an azoospermia.

The After-effects of Head Injuries.—Mental disturbances which follow injuries to the head are by no means the only factors to be considered in these frequent traumata. There is a long list bearing upon the impairment of certain special intellectual faculties. T. Crisp English (Lancet, Feb. 27, 1904) states that traumatic amnesia of some kinds is very common, varies greatly in degree and may be temporary or permanent. Agraphia as a consequence of cerebral injuries may persist indefinitely. It occurred in an officer who had been shot through the head in South Africa, in which, fifteen months after the injury, he was apparently absolutely well, with the exception of a total inability to write. The musical faculty is sometimes lost while others are retained. Some patients who are unable to speak a word can sing it. The arithmetical faculties may be lost; it having been recorded in numerous instances that clerks apparently perfectly well, had, after cerebral injury, been unable to add up a single column of figures. In the diagnosis of these various conditions, malingering and exaggeration must always be remem-

bered. Hysteria, neurasthenia, syphilis and gout should be carefully excluded. The conclusions as to treatment are as follows: (1) In rather more than half of the cases cure may be brought about by medical measures; prolonged mental rest and the proper administration of mercury are the essential points. (2) In a few of the cases the symptoms are mainly due to chronic osteosclerosis and such cases may be almost certainly cured by trephining. (3) In the remainder of the cases the symptoms are more persistent and do not yield to general measures or to the removal of thickened bone only. The author believes that in such cases these symptoms are the reflex results of lesions or irritations of the dura mater; and if the injury has involved the vault of the skull cure can be effected promptly by excision of the thickened or adherent dura mater and removal of any other source of irritation which may be present.

Otto Schmidt's Treatment of Cancer.—Ours is not the only public infested by the octopus called "quack." John Shaw (Med. Press, March 16, 1904) states that while journeying in Switzerland, he took occasion to study, at one month's interval, the effect of this widely advertised treatment on some of his countrymen and women, who had been seduced into taking it. It is the same old story of injections, promised cures, sloughings, delays and ultimate recurrences. The author was unable to obtain any satisfaction from Dr. Schmidt, and when he remarked that a certain patient, who was about to be discharged "with the cancerous process arrested," be sent to Prof. Von Bergmann in order that his opinion as to the alleged arrest might be obtained, Schmidt replied: "Es hat keinen Zweck." In the opinion of the author, it is desirable that before any further exodus of English people takes place, to this sanitarium it should be further investigated.

Fecal Incontinence Treated by Injections of Paraffin.—Broadly speaking, these cases may be divided first, into those cases in which the sphincter ani still retains a small degree of power, and second, those in which it is absolutely paralyzed or is absent. For the latter class of cases, a number of plastic operations based upon the theory of muscle splitting, have been devised, the chief muscles concerned having been the levator ani and the gluteus maximus. A. H. Burgess (Lancet, March 12, 1904) reports two cases of absolute incontinence, one of which was associated with rectal prolapse in which he has obtained great benefit from the submucous injection of paraffin. The injections were made under anesthesia and were placed in several tiers, the upper one commencing as high as the operator could reach. The bunches of paraffin were arranged in threes, so that they may be conceived to have a somewhat similar action to the rectal valves. The melting point in each case was 111° F. In one case 52 c.cm. of paraffin were introduced. This is approximately equal to an ounce and a half. The other patient was a boy who had suffered from complete incontinence of feces from infancy. He had had various operations performed without any improvement being manifest. Two injections were made, the first comprising 6 c.cm. and the second 27 c.cm. There were thus 33 c.cm. or about an ounce injected in all. The dangers of embolism from paraffin injection are well known, but if the material undergoes organization, as it is said to do, this is a danger which in such desperate cases may well be discounted.

Perforation in Typhoid.—The results of intervention in typhoid perforation have as yet not been crowned with the success which was originally hoped for. H. C. Drury and William Taylor (Med. Press, Jan. 13, 1904) report, however, a most encouraging case. It was that of a boy, twenty-one years old, who was suffering from ambulatory typhoid. The second day after admission to the hospital he complained of severe pain. Four hours later his pulse had risen to 120; face was drawn and anxious, the abdomen full and distended. It was tender and tympanitic. Eight hours from perforation with a pulse at 150 and respiration at over 50, the abdomen was opened. The perforation was easily found about 20 inches from the cecum. The opening was closed, together with a second ulcer, which seemed about to perforate. Several pints of warm salt solution were left in the cavity. Time of operation, twenty-one minutes. The heart flickered along at the rate of 150 for two days and gradually got down on the fourth day to 100. Unfortunately there was a local infection in the wound. Twenty-eight days after operation he complained of pain in the abdomen. The symptom persisted and grew worse, the patient became very sick, the temperature was normal, the pulse rose to 116. There was obviously obstruction. An enema produced no effect. The intestines were found extensively matted together, angulation being the cause of the obstruction. Unfortunately the case succumbed from the shock of this secondary operation. Autopsy showed an interesting condition, namely, that there were numerous ulcers which would not have healed for four or five weeks from the termination of the fever.

Radical Cure of Femoral Hernia.—Bottini, Bassini, Kocher, Cushing and others have perfected technics from the treatment of this condition, which in most cases may be depended upon to give permanent relief. J. H. Nicoll (Med. Press, Jan. 6, 1904) describes his operation, which is devised particularly for very bad cases, as follows: (*a*) Obliteration of the sac; expose it, open it, remove its contents, separate it for one inch around the abdominal part of the ring; bisect it longitudinally; make an aperture in one-half near the neck; interlock the halves by putting one-half through the opening in the other; reduce the sac which lies thus bunched up within the abdomen. (*b*) Closure of the femoral ring. Carry a bone-deep incision from the femoral vein along the pubic ramus to the pubic spine. Detach the periosteum and retract it. Drill the bone near its upper edge in two places. By a method which is described in admirable detail these drill holes are utilized as points of attachment for the fascia. The method is in a measure similar to that of Roux who drives a U-shaped staple through the ligament in the bone.

Ambulatory Treatment of Fracture of the Lower Extremity.—A great many continental surgeons pride themselves on being able to have their patients walking within a few days after the occurrence of the fracture. T. H. Openshaw (Lancet, March 12, 1904) describes Hoeffteke's modified Hessing's splint, which he has used with great satisfaction in a large number of cases. So widely is this instrument utilized in Europe that the designer, who was originally a carpenter, now has an immense plant and is a very wealthy man. It is used for fractures of the lower extremity and disease of the elbow, hip or knee. The splint case consists of four minor cases united by steel bands. Heavy leather encircles the thigh from just above the patella to the level of the ischiatic tuberosity behind. This leather opens in front, to be laced up when fitted on. It is fenestrated and lined with flannel. Along each side are clamped firm, adjustable, steel supports, which serve to transmit the weight of the body from the leather casing to the ground. The weight is carried in two ways. First, as above, through the tuberosity, and second through the very accurate fitting of the casing to the thigh. By this double action, the approximated ends of both are not allowed to override. A steel sole

piece with a strong upright on each side is directly continuous with the lateral thigh pieces. This splint is made as follows: A plaster cast is taken of the extremity. This is removed by a split down the outer side, then horizontally across the front of the ankle-joint. This mold is then used to make an ordinary plaster cast of the extremity, and on this cast the leather and casings are built. Most patients can walk with this apparatus without the aid of a stick at the end of a week. The advantages of the splint are obvious, patients who otherwise are obliged to stay in bed being able to go to business at the end of a week or ten days.

Alterations of the Gastro-intestinal Canal in Pernicious Anemia.—Faber and Bloch reported in Gaz. degli Osped. (March 17, 1904): From an accurate study of the intestinal canal in three cases of pernicious anemia, new proof of the statements made in 1889 were found contradicting the view that those alterations described by Nothnagel and his school as intestinal atrophy should be considered post-mortem autodigestion. The authors injected formalin into the alimentary canal and peritoneum directly after death. The mucous membrane of the stomach and intestine was thus preserved. In each of the three cases was found a diffuse gastritis, in two cases the number of the glands was diminished. Some of the glands of the stomach showed a cystic dilatation, the rest nothing abnormal. The stroma was hyperplastic and irregularly infiltrated with round cells. Clinically achylia was found in all three cases. In the intestine no anatomical changes were found, and the minute glandular structure was absolutely normal. No atrophy was found. The authors believe that the gastritis had no etiological relation with the anemia, because cases of pernicious anemia had been observed without achylia, and innumerable cases of ordinary gastritis without anemia. Both the gastritis and the anemia may arise from the same toxic influence, and it is possible that the toxin originated in the intestine. This cannot be demonstrated anatomically.

New Treatment for Fracture of the Neck of the Femur.—The results which are obtained from the usual methods of treating this particular fracture are probably less satisfactory than those following fracture of any other bone in the body. One important reason for this is the mistaken idea which is very generally held by the medical profession that the fracture of the neck seldom occurs except in old people, and hence wrong methods of treatment are instituted from the beginning in young and vigorous individuals who are thus permanently condemned to more or less functional disability. Furthermore, in old people the results are at once recognized as being unsatisfactory and only partial resumption of the function of the joint is even hoped for. R. Whitman (Med. Rec., March 19, 1904) suggests a much more hopeful prognosis for the majority of cases when subjected to an early diagnosis and efficient treatment and points out the frequency with which this condition is met in young and middle aged people. The typical treatment for complete fracture of the neck is the long T-splint to which the body and limb are bandaged, supplemented by the traction force of a weight of from five to seven pounds attached to the foot to resist muscular spasm and to overcome eventually the shortening caused by the upward displacement. It is evident, however, that this method does not prevent more or less movement of the fragments and no attempt is made to secure an accurate apposition of them. In fact in most cases an early resumption of movement is advised in many instances to prevent the patient from becoming bedridden. An impacted or partial fracture is not generally made complete and reduced, although the patient must thus be condemned to partial disability because of direct interference with the function of the joint. Since the deformity which usually results is due to the overriding and adduction of the lower fragment it is urged that this may be most easily prevented by a gradual and forcible abduction of the limb until the trochanter presses upon the pelvis, and then using this as a fulcrum a further abduction will make the capsule tense and thus best direct the outer toward the inner fragment contained within the acetabulum and bring them into more or less accurate apposition. This having been done, a plaster jacket is applied from the mammary line of the chest down to the toes of the affected side, traction and abduction being maintained and care being taken that the jacket fits well around the hips. It is, of course, necessary to first apply cotton and bandages to protect the skin and preferably a jacket of seamless skirting may be used to cover the body and limb. In some cases it may not be necessary to carry the plaster cast below the knee or so high upon the chest. The long spica may be shortened at the end of four weeks, and probably removed at the end of eight. Massage and passive movements may then be used but the limb should not be allowed to support weight for at least four months. In any event, increased and especially persistent discomfort after functional use indicates that the joint is not equal to the work that is required of it and further rest should be demanded. This method should be used in old people as well as the young for the chances of complete recovery in these cases depends more upon complete immobilization and good apposition of the fragments, than upon the age of the patient. Furthermore, the patient may be moved and gotten up to walk with a short spica of the above description long before it would be justifiable with any other appliance, for the immobilization of the parts is more complete. The results from the above methods of treatment have been very successful and have been employed by the author during the past three years.

PHYSIOLOGY.

Effects of Sulphocyanides on Metabolism.—Even less than 0.25 gram of sulfocyanide will give a distinct reaction in the urine with chloride of iron, if given by mouth, according to A. Mayer (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4). After three hours the reaction can no longer be obtained unless a second dose has been given. The total amount of sulphur excreted was high, but neither sulphuric acid nor ether-sulphuric acid was influenced. It seems that sulfocyanides share the properties of other cyanides in inhibiting to some extent the natural oxidation of proteids within the body. Observations on the acidity of urine, show that this is reduced while the amount of ammonia is increased. The excretion by way of the salivary glands is equally as slow as through the urine. Numerous blood-counts made before and after the administration of harmless doses gave no evidence of change.

Amount of Sulfocyanide Excreted in Health and Disease.—By means of a new, very delicate, quantitative method, A. Mayer (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 3 and 4) could prove that sulphocyanide is a constituent of every normal urine and that about 0.05 gm. are excreted in every liter. Smoking seems to increase the amount considerably, but probably only because so much more saliva is swallowed. High figures were obtained after exercise and low ones after excessive perspiration, but in no case examined was this substance absent altogether. In disease, the daily amount stands in relation to the amount of urine voided and all febrile conditions are accompanied by an increased discharge. In general, the author obtained the impression that the saliva is not the only source, but

that sulphocyanides are formed in other as yet unknown parts of the body.

Researches in the Pancreatic Juice.—The quantity of pancreatic juice daily secreted, according to K. Glaessner (Hoppe-Seyler's Zeitsch., Jan. 26, 1904), is about 500 to 800 c.cm. It contains no trypsin, but only a forerunner of the same, which is rendered active by means of the intestinal juice. The fat-splitting and diastatic ferments are strengthened by means of the bile and intestinal juice or only by the latter. The hydrolysis of starch proceeds only as far as maltose, the further splitting of the disaccharides being brought about by means of the intestinal juice. Disaccharides (milk and cane-sugar) are not influenced by the pancreatic secretion. The quantity of juice ferment and the degree of alkalinity are smallest during the condition of fasting, rise soon after a meal, reach their highest point four hours later, to sink eight hours after the beginning of digestion.

The Influence of Various Salts on Pancreatic Digestion.—The alkali salts of the halogens, according to H. R. Weis (Hoppe-Seyler's Zeitsch., Jan. 26, 1904) disturb tryptic digestion to a very small degree, sodium chloride most of all, potassium chloride less and this latter more than the corresponding iodine and bromine compounds of the same concentration. Sodium oxalate has a much more powerfully inhibitory effect than sodium chloride. The sulphates have a greater inhibitory action than the chlorides. Borax has no effect, and the acid sodium phosphate has a favorable action.

Remarks upon Temperature.—The general opinion has always been that temperature is one of the most invariable factors to be observed in the human body, but since the nursing of surgical cases, in particular fractures and other local injuries, has been brought to bear so fully upon numerous cases, it has been observed that under physiological conditions there may be an appreciable degree of variation. M. S. Pembrey (Brit. Med. Jour., Feb. 27, 1904) states that the Darwinian theory leads to the conclusion that the warm-blooded have been evolved from the cold-blooded animals. The temperature of newly born pups, kittens and rabbits falls when they are removed from the warm surroundings of their mother until it reaches but a few degrees above the surrounding air. This, however, is not true of newly born guinea-pigs who incidentally have their eyes open, are thickly coated with fur and are early able to take care of themselves. The young warm-blooded animals may therefore be divided into two classes, those which are blind and helpless and naked and those which are the opposite. These observations were made by Edwards in 1824, but it has only recently been shown that the difference lies in the development of the power of thermogenetic regulation. So far as infants go, Raudnitz has investigated with the view of determining in which class they belong. The conclusions of numerous observations show that the power of regulating temperature is incompletely developed in the newly born infant. The regulation of heat loss is imperfect as well as the regulation of heat production. Maternal instinct has evidently long since anticipated what science has but recently observed, and it is a corollary that the higher and finer the degree of maternal instinct, the less the power of the young to regulate their temperature. The range of temperature in the healthy adult should be determined by rectal temperature alone, the mouth being decidedly irregular. Healthy man shows a range of from 98.8° to 100° F. Certain individuals have been shown to be capable of maintaining a temperature of 101.3° F. without its causing distress. It is important to note that these physiological relations are prone to take place in domestic animals, a fact that should not be forgotten in the exhibition of tuberculin and other tests. Muscular work is considered by the author to be in a measure responsible for heat stroke. It is highly probable that time will show that numerous patients are now kept in bed to be enfeebled thereby simply because their normal temperature is above 98.6° F. The influence of changes in external temperature has probably been correctly interpreted, for it has been truly shown that the yearly average temperature of a man living in the Tropics and the arctic regions is the same. The anesthetized patient cannot regulate his temperature. The combustion of the body is reduced to one-half its normal value and the vital resistance concomitantly decreased. The limits of body temperature compatible with life apparently lie between 75.2° and 114.8° F.

Secretion and Blood-flow of Pancreas.—The fact that secretion continues for some time after complete cessation of the pancreatic circulation, leads O. May (Jour. of Physiol., Feb. 25, 1904) to conclude that there is no direct relationship between the rate of secretion of pancreatic juice and the extent of its blood-supply. By means of the plethysmographic method the author found a suitable means of recording the changes in the blood-supply of the pancreas. This organ is well supplied with vasoconstrictor nerves. The secretion resulting from the intravenous injection of secretin is accompanied by well-marked vasodilatation of the pancreas, which dilatation appears to be secondary to the secretion, probably a result of the action of some catabolites on the vessels.

Investigations on the Liver.—The observation of, diagnosis and treatment of diseases of the liver reveal the utter paucity of the knowledge of the normal and pathological functions of this organ. The researches of L. Brauer (Hoppe-Seyler's Zeitsch., Dec. 19, 1903) seek to broaden the horizon of the knowledge of this subject. It is noted that while normal human bile contains mucin or nucleo-albumin, it contains no coagulable proteid. Traces of the last are found as a cadaveric manifestation and in catarrh of the biliary passages. Larger quantities are present in hepatic congestion, typhoid and parenchymatous nephritis. It has also been discovered in fatty and cirrhotic liver, but not in amyloid or carcinoma. "Albuminocholia" connotes this condition. Normally in the intestine the bile is partly absorbed, nearly all of its water and a large part of its acids. The latter are carried again to the liver where they stimulate a further secretion of bile. For this reason the bile obtained by means of an artificial or natural biliary fistula is not quantitatively identical with that produced under the influence of the normal circulation of the biliary acids. Without the normal stimulus of the latter upon the hepatic function the quantity and quality of the bile are materially lessened. This peculiar circulation of the important constituents of the bile led the author to investigate whether drugs administered for their effect upon the liver undergo a similar circulation. This is found to be the case with methylene blue, which is interesting in this connection, inasmuch as it is one of those drugs that have been administered with the view of controlling infectious catarrhal processes in the biliary passages, particularly those that result in the formation of calculi. Indeed, it has been found that under the influence of methylene blue, cholecystitic manifestations recede and there is a corresponding diminution of coagulable proteid in the bile. The excretion of methylene blue in the bile exceeds the excretion of this substance in the urine during the first few hours after its administration. These facts are of extreme interest for the light which they throw upon the etiology of diffuse diseases of the liver. They tend to

support the hypothesis that hepatic cirrhosis, as for example, in chronic dyspepsia, may depend upon the absorption from the intestine of toxins, which undergoing an intermediate circulation like that of the biliary acids and methylene blue, act upon the liver more profoundly than upon any other organ such as the kidney, which, although it in the long run excretes these toxic products, at any rate does not suffer from the repeated circulation of these substances through its parenchyma. It is well known that methylene blue is excreted by the kidneys partly in the form of reduction products known as "leucobodies." This is also true of the methylene blue excreted in the bile. This fact is of importance from the standpoint of hepatic antisepsis, inasmuch as these leucobodies in themselves are non-toxic. Under normal conditions human and animal bile contain no sugar. During the first few days of pancreas-diabetes sugar appears in the bile. Naunyn found the condition of glycocholia in the diabetes produced by puncture of the floor of the fourth ventricle. The author found that ethyl- and particularly amyl-alcohol easily pass into the bile. Moreover, alcohol shows a greater preference for the bile than for the urine. These facts coincide with the clinical experience that chronic alcoholics suffer more frequently from hepatic than from renal diseases. The anatomic interpolation of the liver in the portal circulation would naturally expose this organ to the influence of toxic agents administered per os more than any other gland. The results of the author not only indicate the easy passage of alcohol through the liver, but also the fact of greater importance, namely, the irritation of the hepatic parenchyma resulting from this passage. Always after relatively large doses of alcohol taken on an empty stomach, coagulable albumin appears in the bile, more in the case of amyl- than in the case of methyl-alcohol. In this instance there is a more marked tendency to the appearance of albumin in the bile than in the urine. Cirrhosis of the liver, which is considered as a typical drunkard's disease, has never been experimentally produced. That it results from the irritation of the alcohol is indicated by the experiments of the author, for just as albuminuria indicates a damage to the parenchyma of the kidney, so albuminocholia indicates a lesion of the parenchyma of the liver. The frequent occurrence of acute hepatitis after the generous imbibition of alcohol is also easily explained by these experiments. Moreover, under the influence of alcoholic intoxication there appear in the bile isolated epithelial casts of the fine interlobular biliary passages, as well as a form of hyaline casts. In normal animals these are not found. The casts are evidence of an ascending catarrhal cholangitis, the result of an intoxication. The casts are produced either by a direct injury of the biliary passages by means of secretory phenomena in the latter, or by the stimulation of the interlobular bile ducts by the alcohol flowing by in the bile. Cylindroid casts have been found in the gall-bladder in cases of typhoid and cholera, as well as in hypertrophic cirrhosis and in the large clinical group of cases of icterus presenting toxic and infectious manifestations. Hanot's cirrhosis has been attributed to a catarrh of the bile ducts, and the known forms of icterus to an obstruction of the interlobular bile-ducts with liver cells, epithelia of the biliary passages and detritus.

NEUROLOGY AND PSYCHIATRY.

Surgical Treatment of Epilepsy.—The unsatisfactory results in the treatment of epilepsy by means of the bromides has led to various more or less hazardous surgical procedures with the aim that the irritative cause of the explosion might be removed. Some two hundred cases have been reported in which a bilateral excision of the superior and middle cervical sympathetic ganglia was done. S. D. Hopkins (N. Y. Med. Jour., March 5, 1904) reports five more cases, one of which was particularly severe but has, since the operation, remained free from convulsions for a period of over two years and hence is considered a cure. The other four cases have been greatly improved, one of them having been without an attack for the past six months. All of them had been previously treated with the bromides without benefit. The removal of the ganglia is followed by several notable disturbances. In three of the cases the pupils remained contracted and acted sluggishly to the light. In the other two cases, one pupil was dilated while the other was contracted. All cases showed a congestion of the conjunctivæ and face, ptosis, increased flow of nasal mucus and a decrease in the pulse and respiratory movements, a decrease in the former of five to thirty beats being noted when the ganglia were divided. The function of the cervical sympathetic is to control the muscular action of the cerebral blood vessels, to transmit impulses from the stomach, intestines and lungs, and to enervate the dilator muscles of the pupil. The most probable theory of epilepsy is that there is a circulatory disturbance in the brain, and since the cervical sympathetic ganglia contain the vasoconstrictor nerves, the excision of these structures will prevent spasms of the blood vessels. A permanent dilatation thus increases nutrition and assists the removal of toxic substances. The excision of these ganglia also prevents the transmission of impulses from the viscera and is, therefore, necessarily of value in reflex epilepsy.

Motor Symptoms of Mania and Melancholia.—Any theory of the origin of these conditions and of the origin of delusions arising in patients suffering from them is welcome. W. H. B. Stoddart (Lancet, March 5, 1904) states that he observed some years ago that melancholiacs suffer from paralysis and rigidity of the muscles of the spinal column and of the large proximal joints, the movements of the wrists and smaller joints being comparatively unimpaired. The attitude of the melancholiac is one of general flexion and adduction, the shoulders being raised owing to the rigid retraction of the upper part of the trapezius. In a severe case the patient cannot raise the elbows above the level of the shoulders, and in profound melancholiac stupor, he stands in the attitude of general flexion with adduction. If, however, there is associated some degree of restlessness, this naturally shows itself in those movements which are least paralyzed, viz., at the wrists, fingers, ankles and toes. For this reason, the melancholiac usually stands, rigidity of the hips rendering sitting uncomfortable. The movements of mania contrast very strikingly with those of melancholia. A maniac in a state of motor excitement moves, for the most part, from the large proximal joints. When a maniacal woman runs, there is an exaggerated movement at the hips, whereas in the running of a sane woman, there is almost none. When a maniac moves his arms, the greatest movement takes place at the shoulders, there being little or none at the wrists and fingers. The maniac shakes hands from the shoulder, the melancholiac from the wrist. In the maniac the attitude of prayer is with hands upraised, in the melancholiac the hands are clasped before the sternum. Experimental psychology has shown a most interesting relation of a normal individual to these phenomena. If such a person's arm is allowed to play upon an automatoscope, and the mind allowed to be absolutely indifferent, the instrument records a slight normal tremor. If now the patient be given an unpleasant stimulus such as the smell of asafetida, *adduction* of the arm is recorded. If, on the other hand, the stimulus is pleasant, viz., heliotrope, *abduction* of the arm is shown by the in-

strument. The author goes on to weave an interesting theory as to the origin of the delusions, which is based upon the belief that they take their rise directly from the disabilities produced by muscular spasms and paralysis. Thus the delusions of the melancholiac are to be traced from his general feeling of inactivity. The exaltation of the maniac arises in a corresponding way from the feeling of activity produced by the stimulation of his cortical neurons. He feels strong and capable of the most wonderful feats. This gives him the idea of power, and the delusion that he is the king or God.

A Salt Solution in Locomotor Ataxia.—The injection of a mixture of 250 c.c. $\frac{m}{8}$ sodium chloride, 125 c.c. $\frac{m}{8}$ sodium sulphate, 120 c.c. $\frac{m}{12}$ sodium citrate and 5 c.c. $\frac{m}{8}$ calcium chloride into the subcutaneous tissues of a man suffering from tabes, causes, according to S. A. Matthews and O. A. Brown (Am. Jour. Physiol., April 1, 1904), pains and other sensations similar to those experienced in the earlier stages of the disease. This occurs even though it has been years since such pains were first felt. The pains decrease successively after each injection, until about the fourth or fifth, after which they may not occur at all. The author cannot state whether such injections have any therapeutic value, though the effects of the latter are of physiological interest. It is possible that the remarkable localization reaction may be of diagnostic value. Injections into persons who did not have locomotor ataxia do not produce similar sensations.

Cerebrospinal Influenza.—Influenza is a chameleon-like clinical entity, says Weljam Owitsch (Med. Obosrenije, No. 22), which offers great difficulty to the clinical experimenter, and is with great difficulty distinguished from typhoid or malaria. Each epidemic shows great variation of the individual characteristics of the virus of influenza. The effect of the poisoning depends on the individuality of the patient. Every patient possesses a locus minoris resistentiæ, and, for example, in phthisical patients the lungs are especially liable to attack. In neurotic patients the cerebrospinal symptoms are easily developed. Delirium and alteration of consciousness are the results of a toxemia affecting the centers in the brain. A characteristic of influenza is a slowing of the pulse (toxic effect on the vagus), and slightly increased temperature. The purely nervous forms of influenza are not often mentioned in literature. Weljanowitsch records the history of a soldier in good condition, with a urethritis, who developed weakness, vertigo, loss of appetite, and suddenly had convulsions, with sudden loss of consciousness. Later, delirium developed. In this case a central irritation from the urethritis, or an embolism of the cerebral arteries, a uremia, or an intoxication following an infectious disease. The author diagnosed the case as influenza. Weljanowitsch came to the conclusion that the cerebral symptoms and cardiac symptoms are frequent in influenza. He advises digitalis, caffeine, strychnine or strophanthus as curative agents.

Cardiac Paralysis in Toxemia.—Beriberi has, like diphtheria, a special influence of a degenerative nature on the cardiac muscle, according to Stanley (Gazz. degli Osped., March 5, 1904), and may produce cardiac paralysis. Such states of toxemia act in the same manner as poisoning by arsenic, alcohol, or by typhoid fever, rheumatism or influenza, all of which may produce a neuritis. The degeneration of the myocardium in beriberi or diphtheria is not due to a neuritis of the vagus, but is due directly to the influence of the toxin on the cardiac muscle. The cardiac paralysis never appears suddenly as a fully developed lesion, but is developed gradually, following cardiac weakness, increasing gradually in consequence of a degeneration of the myocardium. The fact that in beriberi cardiac paralysis appears with the same frequency as in diphtheria ought to make the prognosis of both diseases serious. Stanley, in the British Medical Journal, reports that in 500 cases of diphtheria observed by him, 30 died as a result of cardiac paralysis; 446 cases showed a change of the pulse. Of 341 cases of beriberi, 31 died of cardiac paralysis, 254 showed a diminution in the tension of the pulse, from which one may conclude a degenerative change in the myocardium.

The Source of Tonic and Clonic Epileptiform Convulsions.—According to different experimenters the convulsion center is spinomedullary, medullary, basilocortical or cortical, and insufficient distinction has been made between tonic and clonic spasm. So Nino Samaja (Revue Méd. de la Suisse Romande, March 20, 1904) instituted an extensive series of experiments on green frogs, rabbits, and new-born and adult guinea-pigs, cats and dogs. In each case the intact and healthy animal was subjected to the alternating street current for one second, and again after various curettings or sections of the central nervous system. The electrodes were placed in the different apertures or regions of the body according to circumstances, as, head, mouth, anus, etc. The author reaches conclusions as follows, with the understanding that the word "center" is used to designate that part of the cerebrospinal axis, whose stimulation excites tonic or clonic contractions: (1) The cortical motor area is the exclusive center in the adult dog and cat; the rest of the cerebrospinal axis gives only tonic convulsions. In the frog, the new-born dog and cat, the rabbit and the guinea-pig, the motor cortex, is not the seat of a convulsive center. (2) In the guinea-pig and the rabbit the medulla or the cerebral isthmus are the sources of clonic convulsions; in the guinea-pig and the frog the bulb isolated from the isthmus. (3) In all the mammals the spinal cord is the exclusive center for tonic contractions; it never gives rise to clonic spasm. In the frog, however, the cord is a clonic center. Thus, we find that the clonic convulsive center rises progressively from the cord to the cerebral cortex with the rise from the lower to the higher animals. It is situated in spinal cord and medulla in the green frog, in medulla in the guinea-pig, at the base of the brain in the rabbit, and in adult cats and dogs it is in the cerebral cortex. In man the seat of tonic convulsions is exclusively basilar, while that of clonic convulsions is cortical, and even at birth the motor cortical area is excitable. The type of clonic convulsions in man is partial Jacksonian epilepsy.

Hysterical Skin Symptoms and Eruptions.—The importance of recognizing these peculiar and interesting conditions cannot be overestimated. Thomas D. Savill (Lancet, Jan. 30, 1904) has met with seven different kinds of hysterical skin symptoms: (1) Attacks of generalized pallor of the surface; (2) attacks of flushing; (3) fugitive localized patches of congestion suddenly appearing and disappearing; (4) dermatographia; (5) acroparesthesia and erythromelalgia; (6) urticarial and other hemorrhagic exudations; (7) localized ischemia. The first three are quite peculiar to the emotional vasomotor neurosis which we call hysteria. The remaining four are more frequently met with in so-called hysterical subjects than in others. The author cites a large number of cases which had come under his observation, presenting the greatest variety imaginable of apparently inexplicable symptoms. It is true today, he says, as it was in 1682, when Sydenham wrote: "Whatever part of the body it (hysteria) attacks, it will create the proper symptom of that part. Few of the maladies of miserable mortality are not imitated by it."

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 7, 1904.

THE NEW BELLEVUE.

In connection with the presentation of plans for the new Bellevue Hospital, we give this week a short sketch of the history of old Bellevue. It may well be called old Bellevue, since the main building with its wings dates practically entirely from the beginning of the nineteenth century, having been finished in the second decade. The never-ending wonder is that so much reasonably good work has been accomplished at Bellevue in recent years, notwithstanding all the drawbacks presented by the time-worn old structure and the amount of infectious material of various kinds that it has necessarily gathered, some of which has so soaked in that it will be impossible ever to remedy the evils it is sure to produce. In this age of hospital progress Bellevue has been a crying shame for the city of New York for nearly a quarter of a century, and no American medical man has ever thought of bringing a foreign member of the medical profession to visit it without profuse apologies for the conditions there.

Its existence in its present shape is all the more to be deprecated, since the advance in the building and equipment of hospitals throughout Europe, which is popularly supposed to be so effete and backward, has been so striking in recent years. One of the most interesting features of Moscow, and one that surely aroused the admiration and the envy of the members of the American medical profession who visited that city on the occasion of the International Medical Congress some six years ago, was undoubtedly its magnificent set of hospitals. Out in the university quarter, in what is known as the "Fields of the Virgins," because it formerly belonged to a Russian religious order of women, there are a number of handsome buildings, each housing a separate department of medical or surgical practice. Gynecology and obstetrics have their building, medicine and surgery each a building, nervous diseases a special building, ophthalmology a building. All of them are comparatively new, all built within the last fifteen years, handsomely fitted up, thoroughly modern in their appointments and all of them are fittingly maintained. Yet this is the land where the poor are supposed to be least the subject of consideration, where the Russian peasant, if we would believe ordinary tradition, is still scarcely better than a slave and where modern progress has had least effect upon the life of the people.

Republics are said to be ungrateful, which may be true, for one thing is sure that the only city in Europe which has old hospitals to compare at all with Bellevue is Paris, though it must be recalled that the French capital has also some new handsome city hospitals. Those who have visited Rome in late years will remember the magnificent new hospital only recently completed, situated not far from the railroad depot in one of the most salubrious parts of the city. In Vienna we are prone to think of the General Hospital as typical of the city, but it must not be forgotten that while the old Krankenhaus has been left almost in its original condition, there are at least three magnificent new hospitals in Vienna that will compare favorably with such institutions anywhere in the world. As for Berlin, under the leadership of Virchow, who considered that he could do nothing that would be more worthy of his fame, of his great scientific knowledge and of the interest he had taken in the poor, since the days when, as the result of his investigation into the famine conditions in Silesia, he became a Socialist and suffered for his views, the capital of Germany has secured for itself the finest set of hospitals in the world. Some ten years ago a resolution was passed appropriating during the course of the following fifteen years, about five million dollars to be spent in the erection of suitable hospitals for the city's sick poor. As the

result of that there have come the model hospitals of the world in many respects, and the great German people have shown that their practical genius is ready to apply itself not only to the problems of industrial development but also of care for their ailing poor.

In a word, New York, the metropolis of the great Western Republic, has in the matter of public hospitals, stayed far behind all the rest of the world. We have, in private hospitals, some that we may well be proud of and in which indeed foreign medical, and especially surgical, visitors find many suggestions for their work at home. Why the great city of New York itself should be behind private charitable corporations in this matter of appropriate provision for its sick poor, must remain a mystery. It is to be hoped that now at last the disgrace is to be wiped out and New York is to show that she is ready to do what is after all only her plain duty in the matter of taking care of the poor who have no other recourse except public charity.

At the present time the conditions for the development of a new Bellevue are more favorable, we venture to say, than they have ever been before. Under the management of the Board of Trustees, as constituted by the amendment of the Greater City charter, which became effective in 1901, Bellevue and the associated city hospitals have been so well conducted, considering the many handicaps under which they labor, as to be a source of admiration and encouragement for all who are interested in the care of the ailing poor. The energetic enthusiasm of Dr. Brannan, the president of the Board of Trustees, has shown itself especially capable of arousing the cooperation of all those connected with the city hospital work. It was to be expected that Dr. Brannan would evolve some such worthy plan for the renewal of Bellevue as is now proposed. It will certainly be too bad if New York City should refuse to accept the opportunity to do itself justice that is thus provided for it.

When millions of money are being spent on libraries, museums and various other public buildings, it would be discouraging to think that only the sick poor, those who can help themselves least, are to remain the subject of the unfortunate conditions that have existed in the past and still remain. Medical men have laid down their lives and are laying down their lives even in our own time, in the care of the city's poor. Present conditions increase their dangers. This is unworthy of what we hope is to be the greatest city of the twentieth century and the beginning of the correction of this state of affairs should come at once. Let us have a fitting replacement of Bellevue, according to the plans of the present Board of Trustees and then New York will live up to her past and nobly redeem her fair fame for the care of the poor.

SERUM TREATMENT OF TUBERCULOSIS.

As is well known, the treatment of tuberculosis in the human being by active immunization with the intracellular toxins of the tubercle bacillus, obtained from human tuberculous material, has not yielded very encouraging results. Attempts have accordingly been made to reach the desired end in other ways.

Especially noteworthy in this respect are the experiments of Maragliano, who apparently succeeded in obtaining a tuberculo-antitoxin in a manner quite analogous to the production of diphtheria antitoxin, viz., by immunizing animals with aqueous extracts of tubercle bacilli, which had been prepared at different temperatures. To judge from the available data, however, the resulting product is not sufficiently active as to warrant its more extended application. Marmorek's experiments in the same direction, in which the bacilli were grown on leucolytic sera with the idea of stimulating their production of toxins have similarly not led to a satisfactory issue.

More encouraging are the results which have been obtained by active immunization with tubercle bacilli of diminished virulence, in other words, by vaccination. Koch and Schütz, it will be recalled, have claimed that the bovine tubercle bacilli are not identical with the type found in man, and that it is not possible to produce tuberculosis in cattle by the injection of the human variety. This has proven erroneous, however, and it is now well established that heterologous infection is after all possible. The two types only differ in their degree of virulence, in so far as each has lost its infectiousness to a certain extent for the heterologous host. With this basis given it appeared quite likely that it would be possible to actively immunize cattle against tuberculosis by means of human tubercle bacilli. Extensive investigations in this direction by von Behring have fully borne out the correctness of this surmise, for he succeeded in almost completely protecting animals in this manner against subsequent infection with virulent bovine bacilli. As Ehrlich and Brieger had shown in corresponding experiments that tetano-antitoxin appears in the milk,

it seemed quite logical to infer that it would be possible to produce a passive immunity against human tuberculosis by feeding infants with milk from cows that had previously been actively immunized in the manner indicated. It appears, however, that a prophylactic treatment of this character is not possible, as the serum of the immunized cattle does not contain any specific antitoxic or bactericidal antibodies, which could pass into the milk. While a material advance in this direction is accordingly not to be anticipated, the question naturally suggests itself whether it would not be possible to protect the human being by prophylactic injections with bovine tubercle bacilli. The possibility certainly is there, but under existing conditions it scarcely seems justifiable to make the necessary experiments. While this line of advance is thus closed there are still other paths along which the problem can be attacked.

Especially interesting in this connection are the experiments of Möller, who found that it is possible to accustom tubercle bacilli to a lower temperature than that of the human body. By experimental production of tuberculosis in blindworms he thus obtained a culture which only grew between 20° and 25° C. and died at a higher temperature. This growth proved entirely avirulent for warm-blooded animals, but was capable of producing prophylactic immunity against subsequent infection with virulent tubercle bacilli, as Möller proved in his own person. A curative effect upon animals, however, which had previously been infected could not be demonstrated.

A further advance has recently been reported by Pröscher from Pappenheim's laboratory. He suggests the necessity of simultaneous active and passive immunization of the already infected organism with antitoxin serum and toxin (antituberculin and tuberculin). The object of the antitoxin treatment is the neutralization of the tuberculotoxin, bearing in mind that an immunizing effect is obtained nevertheless even though the toxin solution has been completely neutralized by antitoxin.

Pröscher's procedure is the following: Starting with blindworm tuberculotoxin, which is isolated according to a special method, he produces an antitoxin serum of high potency by active immunization of appropriate animals. Guinea-pigs, which have previously been inoculated with human tubercle bacilli are injected subcutaneously with the resulting serum, and at the same time intravenously with the blindworm tuberculotoxin. This is then repeated with increasing doses according to the condition of the animal, either daily or every other day. Pröscher regards his results as quite encouraging and believes that he will shortly be in a position to obtain an antiserum which will meet all the demands that can be made of such a product in the attempt to successfully combat human tuberculosis. Further details of the experiments which are now in progress in Pappenheim's laboratory will be anticipated with much interest.

A NEW OUTLOOK IN THERAPEUTICS.

The recognition of the protozoan genus, *Trypanosoma,* as the chief etiological factor in the production of several tropical diseases, including the affection commonly known as "sleeping sickness," lends general interest to the methods proposed for attacking these parasites.

At the recent meeting of the American Association of Pathologists and Bacteriologists, Prof. Ehrlich, of Frankfort, reported the results of his experiments with a compound which possessed specific action upon one of the members of this group. A more complete account of his labors in this field, which were carried on in collaboration with Shiga, has been recently published (*Berliner klinische Wochenschrift,* 1904, Nos. 14 and 15), from which a number of suggestions may be gathered.

Although it seems reasonable to make use of the immunizing agency of specific antitoxins, the success of certain pharmacological products, such as quinine in malaria, lends support to the suggestion that chemical agencies may be made equally efficient. Their production and application is usually more simple than those derived from bacterial sources, especially when the higher protozoan organisms are under consideration. Laveran and Mesnil have had more or less success in their experiments with arsenate of soda in certain tropical animal diseases caused by the *Trypanosomata,* the unfavorable results being due to the chronic arsenical poisoning which appeared.

Ehrlich and Shiga made use of stains derived from the benzo-purpurin series and succeeded with a combination which they have called "trypanroth" (trypanred). They found that by the injection of a one per cent. solution of this substance in mice, a diffuse coloring of the skin and internal organs took place which lasted from six to ten weeks. They were next able to prove that mice injected with the coloring matter and blood

containing the trypanosomes, did not become diseased.

Similarly favorable results were secured when the solution was injected three days after the infection had taken place and the animal's blood was laden with the parasites. Recurrences were noted but they did not occur until after a considerable period (sixty-five days). An interesting fact is that the same good effects were noted when the substance was given by mouth. Mice that were fed with the drug for some days were able to stave off the infection entirely or were but slightly affected. The question as to whether the same good effects are seen in other animal species, has not been fully answered by the experiments thus far undertaken.

The authors believe, however, that closely related chemical products will be found to overcome the somewhat more unfavorable results seen in the other animal species experimented upon. It is of importance to know by what means these stains accomplish their purpose. Ordinary germicidal properties cannot be assigned to them as it was found that the trypanosomes were only destroyed within the animal body under conditions which could not be reproduced outside of the latter.

Further experiments also, showed that the protection called forth by the presence of the drug in the body only lasted a few days, but it was also demonstrated that a certain degree of immunity was conferred in those animals which had been infected and subsequently cured. The immunity, however, was limited, as shown in those cases where recurrences took place in sixty-five days.

Aside from the possibilities of their practical application, these observations are of interest in other ways. They apparently throw some light on the question of the manner of the recurrences in other diseases, such as malaria and syphilis. For these diseases it may also be assumed that the appearance of a recurrence may be ascribed to a transitory and more or less rapidly declining immunity and the effectiveness of a certain number of residual germs. It ought not to be a difficult matter to prove this experimentally in the case of malaria, by attempting to reinfect the individual after a cure had been accomplished by means of quinine. The time which elapsed before reinfection took place would then correspond to the immunity conferred by the quinine.

Another important result gained by these observations is, that they point to some bond of connection between immunity and cure produced by pharmacotherapeutic agencies. For it was shown that the trypanred which is analogous to other better known drugs, gave rise to conditions which led to an active immunity. Immunity secured in this way may possibly be more effective than that produced by specific sera, for during the activity of the latter, part of the receptor apparatus of the parasite is taken up which is consequently rendered inactive in so far as the actual production of antibodies is concerned. The possibilities offered by this new field of research are of far-reaching interest and importance.

ECHOES AND NEWS.

NEW YORK.

Measles Prevalent.—Measles is spreading at an alarming rate, according to Health Department figures, and its prevalence is declared to be greater than was ever known before. In many cases, too, it is followed by bronchopneumonia. Last week's report showed 1,630 cases in the five boroughs, with 37 deaths from measles and 135 from bronchopneumonia. Since Jan. 30, when there were 814 cases, the increase has been steady.

New York School of Clinical Medicine.—At the meeting of the Medical Board of the New York School of Clinical Medicine held April 9, Dr. J. L. Adams was elected Secretary of the school and professorial and other distinctions were conferred upon the following in the departments specified: Mental Diseases: Prof. E. C. Dent, Superintendent, Manhattan State Hospital, West, Ward's Island. Internal Medicine: Prof. Wm. Brewster Clark, M.D.; Gastro-intestinal Diseases: Prof. Robert Coleman Kemp, M.D., Associate Prof. Graham Rogers, M.D.; Hydrotherapeutics: Prof. Alfred W. Gardner, M.D.; Ophthalmology and Otology: Prof. Geo. Ash Taylor, M.D.; Clinical Instructor and Assistant, Wm. E. West, M.D.; Genito-urinary Diseases: Chief of Clinic and Associate, Prof. C. Stern, M.D.; Dermatology: Chief of Clinic and Instructor, L. D. Weiss, M.D.

State Civil Service Examinations.—The State Civil Service Commission announces general examinations on May 21 for the following positions: Apothecaries in State hospitals and institutions; resident physician and superintendent of nurses at the State Hospital for Tuberculosis; physicians in State hospitals and institutions of both regular and homeopathic schools. Address Chief Examiner at Albany.

Gift to Post-Graduate Hospital.—New York Lodge of the Benevolent and Protective Order of Elks held, on May 5, a ladies' social session in their Lodge rooms at Elks' Hall, Fifty-eighth Street and Eighth Avenue, and dedicated two beds which are to be endowed in the Post-Graduate Hospital. The contract was signed, and there were appropriate ceremonies. Mr. Champe M. Andrews made an address on behalf of the Lodge; Dr. D. B. St. John Roosa spoke on behalf of the Post-Graduate Hospital, and John J. Delany, corporation counsel, spoke of the charities of the city.

New Fordham Hospital.—Plans for the group of new Fordham Hospital buildings to be erected by the city at Crotona Avenue and the Southern Boulevard were filed yesterday at the Building Department. The structures will include the main hospital building, five

stories in height and standing on a plot 305 by 43 feet; a four-story power house, which will also contain a laundry and servants' quarters; a two-story brick stable and morgue, and a five-story nurses' home. The total estimated cost of these buildings is $560,315, of which $339,000 will be spent for the hospital itself, $129,000 for the power house, $52,315 for the stable and morgue, and $40,000 for the nurses' quarters. The plans were prepared by Architect Raymond F. Almirall.

Appeal for a Woman's Hospital.—An appeal for funds has been sent out by an organization concerned in the establishment of a hospital for women, for the purpose of affording relief to incurable cancer patients and for the treatment, study, and prevention of cancer. The hospital will be located in this city, and will be known as the Fairhaven Sanitarium. In the circulars issued by the organization the Commissioners of the State Board of Charities are said to have declared themselves satisfied with the necessity of such an institution as the one contemplated, as there is only one hospital in this city—the Montefiore Hospital—which admits incurable cancer patients. Before the Board of Managers can begin making any arrangements to incorporate and open the new hospital, however, $10,000 must be in hand. The dues have been fixed at $10 for annual members, $100 for life members, and $1,000 for patrons. Contributions for any amount will be received by Henry R. Wilson, President of the Lincoln Trust Company.

New Professorship of Pediatrics in Columbia.—Two gifts to Columbia University were announced by President Butler at the meeting of the Trustees Monday afternoon. The first was $60,000 from Horace W. Carpentier of the class of 1848 for the support of a chair in the Medical School in memory of his brother, the late Dr. Ruben S. Carpentier. The trustees voted to apply the income of this fund to the Chair of Pediatrics (diseases of children), and in recognition of the gift they named the chair, the incumbent of which is Dr. L. Emmett Holt, the Carpentier Professorship of Pediatrics. Dr. James R. Hayden was appointed Clinical Professor of Genito-urinary Diseases, in succession to Dr. Robert W. Taylor, who handed in his resignation to take effect on June 30. Dr. Arnold H. Knapp was appointed Clinical Professor of Ophthalmology.

Manhattan Dermatological Society.—Regular monthly meeting held Friday evening, April 1, 1904, at the residence of Dr. G. W. Crary, with Dr. Oberndorfer presiding.

The following cases were shown: Dr. Edw. Pisko presents five cases. (1) Lichen planus circinatus; the lesions in a girl of twelve years were best seen on arm and upper thigh; other typical papules were observed on the chest, abdomen and limbs, and a few on the face; the question of differentiating ringworm was decided by negative microscopic findings. Scratch marks on the thighs show the development of lichen papules. Dr. Oberndorfer saw this type on the penis in a general lichen of the body. Drs. Gottheil and Crary could not explain the evolution of circinate lesions except by coalescence of groups of papules; the healing center was rare. (2) A young man with characteristic syphilitic mouth lesions and a single circinate lesion on skin near inner canthus of left eye. The lesions in general outline and aspects resembled ringworm, but microscope decided negatively. Drs. Abrahams and Gottheil said the throat lesions and the negative microscopic findings helped to make a diagnosis of syphilis; the circinate form was rare but often met with in negroes. Dr. Oberndorfer stated that circinate lesions in early syphilis were not uncommon; the continuous margin of distinctly raised papules and their pearly appearance suggested lues. (3) A case of erythema multiforme; the lesions were by no means typical; in fact, the skin showed urticarial lesions; Dr. Pisko stated that the eruption had changed considerably within the past few days. (4) A middle-aged man with a lupus erythematosus of the nose and cheek, illustrating the beneficial effects of local applications of trichlor. acetic acid; a single application to a given area was sufficient; it must be gently applied and not rubbed in, otherwise deep ulceration may result; a small patch was covered at a time; usually 6, 8, or 10 such areas were treated, thus covering the entire patch. He treated eight cases within the past two months and recommended the remedy most highly. (5) A young man showing lichenoid lesions on right half of chest and abdomen and papules on neck; patient stated he used some strong liniment to relieve severe itching of the body; hence the latter lesions were considered traumatic while the papules on neck were regarded as most likely a true lichen planus.

Dr. L. Weiss presented a girl of fifteen years, showing innumerable small punctate pustules on forehead, and large acneform papules on face, with marked oily skin. The forehead also showed a high degree of dermatitis; the latter not artificial. Treatment consisted of soap lotions, peeling pastes, expression of comedones, and curette for large papules. Internally, iron, arsenic and strychnine. Dr. Weiss applied the term, follicular acne to the condition; Dr. Sobel called it acne, although the forehead was unusual; Drs. Moses and Gottheil suggested a mild form of treatment, believing better results would be obtained than by using strong peeling lotions and salves. Dr. Pisko called it acnitis. Dr. Bleiman makes a distinction between this case and one of simple acne; although the process was practically the same in both; the clinical picture was wholly different; he agrees with Drs. Moses and Gottheil in recommending mild treatment; since using the latter method the condition only began to improve. Dr. Crary would apply the term folliculitis to involvement of hair follicles and not to sebaceous follicles. Dr. Geyser stated X-ray treatment was almost a specific in these cases.

Dr. Gottheil presented the following cases: (1) A male with a lesion resembling a dermatitis confined to left index finger; the condition began as small flat pustules about one month ago; these ruptured, leaving a red, dry excoriated surface; neither the flexor surfaces nor the folds of adjacent skin are involved; this fact would tend to exclude it from the eczema class; Dr. Gottheil termed it impetigo circinatus chronicus. Dr. Abrahams said its localization, well-defined margins, slow progression and general aspects favored diagnosis of eczema parasitica. Drs. Crary and Pisko recognized a resemblance to dermatitis repens. Drs. Pisko and Bleiman spoke favorably of the use of 20 per cent. nitrate silver solutions locally applied. Dr. Cocks agrees with Dr. Abrahams in calling it parasitic eczema. Dr. Ochs saw good results from the use of sol. of kali permang. (2) A case of pigmented warts on the penis of three years' duration. (3) A case for diagnosis: A middle-aged woman shows large crescentic erythematous patches with raised margins, slightly scaling, and clear, slightly pigmented centers on both lower limbs; of many months' duration and slow progression; no mycelia found, and KI produced no result. Dr. Weiss entertained a possible diagnosis of erythematous lupus, and the suggestion was well taken by the members. Dr. Moses suggested erythrasms in an unusual location; he will examine scales for the fungus and report result at next meeting.

Dr. Crary showed a young woman with an enlarge-

ment of the sternal end of the left clavicle; present about one year, is getting slightly larger and is somewhat painful and worse at night. Patient gives only an incomplete rheumatic history. Dr. Gottheil said periostitis and thickening in this location was very suspicious of syphilis. Dr. Abrahams likewise called it syphilis. Dr. Moses advocated injection method, as bone lesions responded very slowly to internal medication.

Dr. Ochs presented a male, showing a suspicious sore on penis; of two weeks' duration and slightly indurated; no adenitis, no skin lesions; but throat shows a pharyngitis. Dr. Gottheil termed it a parchment chancre; Drs. Weiss and Abrahams would defer any opinion until two weeks had passed; they would prefer to await further developments.

Dr. Ochs also showed his case of onychorrhexis; he could not furnish any additional information as to its etiology but could report decided improvement in the condition since last presented. The nails seemed to respond to carbolic acid treatment. The patient's nails show decided improvement.

Dr. Oberndorfer presented a male with squamous lesions on both elbows, resembling psoriatic patches; patient had a similar outbreak ten years ago which responded to treatment. Presented as a case of chronic squamous eczema, resembling psoriasis.

Hospital Appointments.—Up to May 1, 98 men from the graduating class at the College of Physicians and Surgeons have secured interneships, graduate students have taken four places, and 11 have been made alternates, making a total of 113. In addition to the two appointments at the Almshouse and Workhouse hospitals, published in the Medical News of last week, two other appointments have been made, viz., Wm. Pincus and J. D. Malcolm. The following is the list for the past week: Passaic General Hospital, J. A. Wheeler, W. J. Duckett. St. Catharine's (Brooklyn) Hospital, E. O. J. Eytinge. Columbus Hospital, A. J. Ghiglione. Moses Taylor Hospital (Scranton, Pa.), H. A. Noble.

PHILADELPHIA.

Address by Dr. Sherrington.—Under the auspices of the medical faculty of the University of Pennsylvania, Professor Charles S. Sherrington, of the University of Liverpool, England, delivered an address in the Medical Hall, Thursday, May 5. The subject considered by Dr. Sherrington was "Cerebral Localization."

Graduate Nurses' Association.—The Graduate Nurses' Association of Pennsylvania met at Wilkesbarre April 20, the attendance being 100. The purpose of the meeting was to frame legislation compelling the registration of all graduate nurses in order to protect the public against impostors. Committees were appointed to urge the matter at the coming session of the legislature.

Meningitis at League Island.—Five cases of cerebrospinal meningitis and one death recently occurred at the League Island Navy Yard and Surgeon General Rixey hastened from Washington to outline plans for controlling the disease. Strict quarantine has been instituted and all the men quartered in tents. The authorities are confident that an epidemic similar to that of last year when 35 cases occurred will be prevented. The present outbreak is believed to be due to importation of the disease by a detachment of marines that recently returned from Panama.

Pasteur Treatment at Home.—The Pasteur treatment for rabies has recently been employed for the first time in this city by Dr. W. L. Forrester. The patient is a boy of four years who was bitten by a dog that post-mortem examination showed to be suffering from rabies. The boy was taken to New York where treatment was begun. He was then brought home and the necessary serum sent on each day and injected by the physician. No symptoms of the disease have developed and the danger limit has been passed for some days.

Phipps Institute.—Dr. Leonard Pearson, State veterinarian of Pennsylvania, has been appointed a member of the staff of this Institute and will accompany Dr. Ravenel on his European tour this summer. They will visit Italy, Holland, France, Sweden, Germany and England, studying the methods of those who have been experimenting with the inoculation and vaccination of both animals and human beings. The data thus gained will be given out by the Institute to the medical profession.

New Seaside Hospital.—The Jewish Maternity Association has purchased a property known as Leith Villa at Ventnor, N. J., which they will equip as a first-class seaside hospital. It will be placed in use during the coming summer in place of the one formerly conducted at Atlantic City. During last summer 326 patients were treated at the home, at an expense of $3,800.

To Disinfect Empty Houses.—A new step in the prevention of tuberculosis has been taken by the Department of Health. This is the disinfection of all empty houses on request of prospective tenants. The only requirement will be that the tenant guarantee thoroughly to clean the building before moving in.

Nurses Receive Diplomas.—Fifteen young women received diplomas at the commencement of the Polyclinic Hospital Training School for Nurses on April 29. Miss Maud Banfield, Superintendent of the hospital, spoke on "State Registration of Nurses." She urges this measure for the following reasons: The protection of the public, the protection of the nurses, and the improvement of educational standards among nurses. The principal objection comes from so-called schools that profess to turn out nurses after a ten weeks' course of lectures in a commercial building or after a course by mail.

Tuberculosis at the Zoo.—The Zoological Society of Philadelphia is to make experiments looking toward the prevention of tuberculosis in animals, this disease being one of the most frequent causes of death. An unused house in the garden is to be converted into a hospital where all new specimens will be received and examined and efforts made to produce immunity to the disease in question.

Tuberculosis Pavilions to Be Opened.—The six pavilions for the treatment of tuberculous patients at the Philadelphia Hospital are to be opened in the near future. They are situated in the extreme northwest corner of the grounds on an elevated site. The pavilions are 27 by 36 feet in size and so arranged that the entire four sides can be thrown open if so desired. Each will contain fourteen beds. The entire structure and the furniture is of iron or glass and the floor of artificial stone, thus allowing of the most thorough antiseptic cleansing of the surroundings of the patients.

Special Clinics for American Medical Association.—The medical schools and hospitals of Philadelphia have arranged for a special series of clinics and laboratory demonstrations as a compliment to the visiting members of the American Medical Association on their way to and from the June meeting in Atlantic City. The clinics will be held during the week preceding and the one following the session at At-

lantic City. The institutions contributing to this series are the University of Pennsylvania, Jefferson, Medico-Chirurgical, Polyclinic, Philadelphia, German, and Pennsylvania hospitals. Lunch to all members will be served each day in the University Hospital. Dr. John B. Roberts, of 313 South Seventeenth Street, will entertain at luncheon on Friday, June 3, at 2 P.M., members of the American Medical Association and of the American Academy of Medicine. The chairman of the committee on clinics is Dr. De Forest Willard, 1818 Chestnut Street.

Wills Hospital.—A meeting of the Wills Hospital Ophthalmic Society will be held Monday, May 9, 1904 at 8.15 P.M. The main subject chosen for discussion is Affections of the Lacrimal Apparatus. Introductory remarks: Etiology and Symptoms, by Samuel D. Risley, M.D.; Bacteriology and Microscopic Study, by Harold G. Goldberg, M.D.; Complications and Sequelæ, by S. Lewis Ziegler, M.D.; Treatment, by Wm. Campbell Posey, M.D. General Discussion by Drs. George C. Harlan, Conrad Berens, Frank Fisher, W. W. McClure, Charles A. Oliver, McCluney Radcliffe, P. N. K. Schwenk, William Zentmayer, and others.

CHICAGO.

Directors and Officers.—At a recent meeting of the stockholders of the Chicago Eye, Ear, Nose and Throat College, the following officers and directors were elected: Drs. Wm. A. Fisher, Adolphus G. Whippern, H. W. Woodruff, Thomas Faith, and John R. Hoffman. The directors thereupon elected Dr. Wm. A. Fisher President and Treasurer; Dr. Adolphus G. Whippern, Vice-President, and Dr. John R. Hoffman, Secretary.

Rejection of Inspection Plan.—Some time ago Mr. Hartung, Trustee of the Board of Education, made a plea for a more rigid examination of school children; but the school management committee of the Board has rejected the plan.

Opposition to the Location for the Erection of Hospital for Infectious Diseases.—As a result of a recent conference between Trustees of the Memorial Hospital for the Treatment of Infectious Diseases and owners of property in the vicinity of the proposed site for the institution, it was decided to call a public meeting of all persons interested in any way in the project to exchange views as to the direct danger of contagion and the benefits to be derived from the establishment of such an institution in that neighborhood. Dr. Billings explained the great need of such an institution in Chicago, and gave a brief outline of what are known as infectious diseases, their effects, and the best methods of treatment. He said there is no possibility of contagion from a properly conducted hospital. There is to-day in Chicago only one place where infectious diseases can be treated, and that is in the addition to the Cook County Hospital. No institution more beneficial to the public of the city of Chicago has been recently proposed. The aim is to treat certain infectious diseases, such as measles, diphtheria, and scarlet fever, in a scientific manner. This hospital is to be established on a purely philanthropic basis at the place where such diseases can be treated and studied from a scientific standpoint, in order that the germs of the disease may be located and proper means be determined upon for its extermination.

Compound Fracture of the Patella and Condyles.—At a recent meeting of the Chicago Orthopedic Society, Dr. A. E. Halstead reported the case of a man who, while riding on the platform of a fast train, was struck by an iron girder, prducing a compound fracture of the right patella. The external condyle of the femur was also nearly separated from the shaft, being attached only by the periosteum. A temporary dressing had been applied by an outside physician before the patient was brought to the St. Luke's Hospital. On September 8 last, the day of admission to the hospital, under general anesthesia, the wound was enlarged and the spicula of bone and the detached external condyle removed. The patella was found to have been broken into three fragments and the patellar ligament completely divided. After thorough lavage of the joint cavity with one per cent. solution of carbolic acid followed by decinormal salt solution, the patellar fragments were united by chromicized catgut suture. The ligamentum patellæ was sutured with mattress sutures of the same material. A cigarette drain was placed in the joint and the skin wound closed by silkworm-gut sutures. The drain was removed at the end of twenty-four hours. Following this a circular plaster of Paris cast was applied. This dressing was not changed for three weeks, when the skin sutures were removed. After this gentle passive movements and massage were practised daily. The result, as was shown, is ideal. The limitation of flexion and extension was but slight; the fragments of the patella have firmly united and the bone was freely movable. A case similar to this was treated by him at the County Hospital a short time ago. In this the patella was sawed through and the condyles partially divided by having the knee come in contact with the circular saw. The joint was thoroughly washed out and a large quantity of blood and foreign matter removed. The patella was sutured with catgut, the fragments replaced and the joint drained for twenty-four hours. In this case the result was all that could be desired. The man now has a freely movable joint, and no appreciable deformity.

CANADA.

Bill to Relieve Medical Students from Examination in the Province of Quebec.—Great interest and much indignation is being evoked among the medical fraternity of Montreal, the province of Quebec and as well among the medical student body over the appearance in the Quebec legislature of another of those bills having for its purpose the making of doctors out of students who have failed to pass the necessary and required matriculation examination. The present bill proposes to admit all who have begun the study of medicine prior to September last without passing their matriculation examination. Regularly qualified students denominate these medical "scabs" of whom there are said to be 260 in number. The profession in Montreal have held a meeting on the matter and are dispatching a deputation to the legislature to protest against this legislation.

Appointments.—Dr. L. deL. Harwood has been appointed to succeed the late Dr. Brennan as Professor of Gynecology in Laval University, and will also be chief of the gynecological department in the Notre Dame Hospital, Montreal. Dr. Harwood has also been chosen President of the gynecological section of the Medical Congress of French-speaking Physicians of North America which meets in Montreal this summer. For thirteen years Dr. Harwood has been connected with the gynecological department of Notre Dame Hospital.

Dr. Frederick Etherington, Kingston, Ont., has been appointed by Queen's Medical Faculty to the newly established tutorship in human and comparative anatomy. Dr. Etherington is now in Edinburgh but will return to Kingston in the early autumn and

hereafter devote all his time to the position to which he has been appointed.

These appointments have been made by Queen's Trustees to the Medical Faculty at Kingston: Professor of Pediatrics and Associate Professor of Obstetrics and Gynecology, Dr. Wood; Assistant Professor of Anatomy, Dr. Mylkes; Professor of Medical Jurisprudence and Toxicology, Dr. Williamson.

The Ontario Cabinet have approved of the following appointments on the staff of the University of Toronto: H. S. Hutchinson, M.B., and W. M. Meldrum, M.S., assistants in the chemical laboratory; R. H. Mullen, M.B., assistant demonstrator in pathology; F. W. Marlowe, M.D., F.R.C.S., Eng., assistant demonstrator in anatomy.

The Ontario Government have in contemplation the appointment of a physician to be general assistant to the various asylums of the province. He will act as a relieving officer.

To Check Consumption's Ravages.—A deputation from the Association for the Prevention of Tuberculosis waited on the Prime Minister, Sir Wilfrid Laurier, at Ottawa, last week, and asked for the establishment of a sanitarium in each of the provinces of the Dominion for the treatment of consumptive patients. It was pointed out to the Premier the need of such as there are annually 8,000 deaths in the Dominion from this disease. The Prime Minister pointed out that the British North America Act provided for provincial jurisdiction over hospitals, but he would consult with the Minister of Justice to see whether a point might not be stretched in this particular instance to provide for the Dominion aiding such institutions.

Montreal Western Hospital.—At the quarterly meeting of the Board of Governors of the Montreal Western Hospital held recently the question of the erection of a new wing was freely discussed, and it was at once decided to open subscription lists towards raising the necessary funds. The medical report for the quarter ending March 31 was submitted and it showed that during that quarter there had been admitted 133 patients, 61 males and 72 females. On January 1, 1904, there were in the wards 34 patients, 128 were discharged, 7 died and there remained 29 at the end of the quarter. In the out-door department the total number of consultations reached 1,783.

A Methodist Hospital for Toronto.—The late Hart A. Massey of Toronto, left $100,000 for the purposes of a Methodist hospital in Toronto, provided a like amount could be raised by private subscription. Now the leading organ of the Methodist body in Toronto, advocates that such an institution be gone on with, and it would appear as though Toronto really needed increased hospital accommodation, as during the past winter all of the hospitals were more than crowded. It is understood that the Medical Faculty of the University of Toronto, look upon it with much favor as the institution would likely be established close to their new medical building.

GENERAL.

American Medical Editors' Association.—The annual meeting of the American Medical Editors' Association will be held on June 6 at 2 P.M., Dennis Hotel, Atlantic City, N. J. Many interesting papers will be presented upon Medical Journalism and allied subjects by editors of recognized ability.

Gift for Tulane Medical School.—Under a decision rendered by the Louisiana State Supreme Court, April 25, Tulane Medical College receives the bulk of the estate of the late A. C. Hutchinson, who at the time of his death was President of Morgan's Louisiana and Texas road. Mr. Hutchinson's estate was valued at nearly $1,000,000 and most of it was left to Tulane University for the use of its medical college in the establishment and maintenance of a clinic and hospital for the sick.

State Board of Medical Examiners of New Jersey.—The examinations of the State Board of Medical Examiners of New Jersey will be held at Trenton, N. J., June 21 and 22. Application for the regular blanks should be made before June 11.

Statement by Prof. August Forel.—From August, 1879, until March, 1898, I was the Director of the Burghölzli Insane Asylum and Professor of Psychiatry at the University of Zurich and desire to make the following statement: Dr. Carl Bertuhringer, who designates himself a representative of the so-called Koenig Medicine Co., of Chicago, and who incidentally represents himself as a former assistant of Prof. Forel at the Burghölzli Asylum, was *never* my assistant and never an assistant at the Burghölzli Asylum. He did indeed study medicine in Zurich and, like other students, studied psychiatry with me, and practised in the Clinic as a so-called "Practikant," as did other students. Under these circumstances I once permitted him to hypnotize *one* patient. But he was never either my private or my asylum assistant and hence has no right to publish himself as such. Another Dr. Bertuhringer (Dr. Hans Bertuhringer) was actually assistant physician in Burghölzli and is now second physician at the Rheinau Asylum, Canton Zürich. But this is quite another person.—Dr. August Forel, former Professor at the University of Zurich, Chigny, Switzerland, April 6, 1904.

Florida Medical Association.—An amendment to the constitution and by-laws of the Florida Medical Association, making Jacksonville the permanent meeting place, has been submitted, and it has no opposition. Jacksonville also gets the president of the association for the ensuing year—Dr. E. N. Liell. The nominating committee of the house of delegates made the following report for officers for the ensuing year, which was adopted and said officers duly elected: President, E. N. Liell, Jacksonville; First Vice-President, J. W. Jackson, Miami; Second Vice-President, J. F. McKinstry, Gainesville; Third Vice-President, J. S. Holmes, Tampa; Secretary and Treasurer, J. D. Fernandez, Jacksonville. Resolutions were adopted strongly favoring a State Board of Medical Examiners. Drs. W. L. Hughlette, J. H. Durkee and J. N. Fogarty were appointed as a committee on revision of the constitution and by-laws, to report at the next annual meeting. A committee from the American Medical Association, relative to the importance of a uniform system of registration of vital statistics, was referred to the committee on legislation to prepare a bill to be presented at the next session of the Florida Legislature and to urge its passage. Following papers were read and discussed: Surgery—Dr. J. N. Fogarty, chairman. Treatment of Trachoma, by Dr. J. H. Claiborne of New York. Report of a Case of Hepatic Abscess, and Report of a Case of Strangulated Hernia, by Dr. J. N. Fogarty, Key West. Remarks on the Pathology and Treatment of Appendix Abscesses, with report of an illustrative case, by Dr. Carey P. Rogers, Jacksonville. Medicine—Dr. Arthur L. Izlar, chairman. Paper on Anchylostomiasis, with exhibition of the parasites, by Dr. Aug. E. Unter, Greenville. Paper on Static Electricity, by Dr. Will White, Live Oak. Treatment of Affections of the Skin by the X-ray; High Frequency and Brush Discharges from a Static Machine, by Dr. R. P. Izlar, Waycross, Ga. Cerebrospinal Fever at Madison, with Report of Cases, by Dr. A. L. Blalock, Madison. A Few Observations on Typhoid Fever, by Dr. J. D. Love,

Jacksonville. Diseases of Children—Dr. J. D. Bennett, chairman. Gynecology—Dr. L. M. Anderson, chairman. Ovarian Abscess; Sarcoma of Breast; Report of Rare Cases Operated Upon, with Specimens, by Dr. Edward N. Liell, Jacksonville. Leucorrhea in Married Women, by Dr. L. M. Anderson, Jasper. Subinvolution of the Uterus, by Dr. R. L. Goodbred, Mayo. Hygiene—Dr. Eduardo Andrade, chairman. Some Remarks on the Bacillus of Diphtheria and Anisokoria (inequality of the pupils), by Dr. Eduardo Andrade, Jacksonville. Paper on Cerebrospinal Fever (?) at Madison, A Report on the Recent Epidemic, by Dr. Hiram Byrd, Madison. Following resolution was adopted and the association adjourned *sine die: "Resolved,* That the Florida Medical Association hereby expresses sincere gratitude to the railroads of the State and the hotels of Live Oak for courtesies extended, to the citizens of Live Oak and the Suwannee County Medical Society for their free-handed, large-hearted hospitality, to the committee of arrangements, of which Dr. T. S. Anderson is chairman, for making the social features of the association a success, and to Col. Frank Drew of the Suwannee and San Pedro Railroad for his special attention to the profession, for furnishing his private car for excursion to Half Moon Lake."

American Proctologic Society.—The sixth annual meeting will be held at Atlantic City, N. J., June 8 and 9. The profession is cordially invited to attend all meetings. This is the program: President's Address, by W. M. Beach, M.D. Things of Specialism and of this Society that Make for Optimism; The Surgical Treatment of Prolapse of the Rectum, by J. M. Mathews, M.D., Louisville; Further Observations in the Treatment of Pruritus Ani with the Roentgen Rays, by J. R. Pennington, M.D., Chicago; My Method of Dealing with Perirectal Infections; Case Reports and Illustrations, by Jno. L. Jelks, M.D., Memphis; A Consideration of the Present Status of the Treatment of Cancer of the Rectum, by Lewis H. Adler, Jr., M.D., Philadelphia; Sterile Water Anesthesia in the Office Treatment of Rectal Diseases, by S. G. Gant, M.D., New York; The Utility and Practicability of the Flexible Rectal Tube, by S. T. Earle, M.D., Baltimore; Polyadenomata of the Rectum; Report of a Case, by G. B. Evans, M.D., Dayton; Some Observations on the Treatment of Rectal Diseases, by Wm. L. Dickinson, M.D., Saginaw; Results of the Treatment of Cases of Obstipation Due to Acquired Valvular Hypertrophy, by Thos. Chas. Martin, M.D., Cleveland; Rectal Valves, with Report of Operative Cases, by Louis J. Krouse, M.D., Cincinnati; Simple Fistula in Ano, by Howard A. Kelly, M.D., Baltimore; The Proctologist; the Necessity for His Being an Accomplished General Surgeon, by Floyd W. McRae, M.D., Atlanta; Clinical Cases, by Jas. P. Tuttle, M.D., New York; Adrenalin and Rectal Diseases, by A. Tierlink, M.D., Gand, Belgium; A Paper, by Geo. J. Cook, M.D., Indianapolis; One Thousand Operations for Hemorrhoids without a Death; with Remarks, by Leon Strauss, M.D., St. Louis.

The Sheppard and Enoch Pratt Hospital, Baltimore.—A Conference in Psychiatry and Neurology will be held at this hospital on Monday, May 9, 1904. Following is the program: On the Nature of the Disease Process in Insanity, by Adolf Meyer, M.D., Director of the Laboratory of the N. Y. State Hospital; Congenital Spastic Rigidity (Little's Disease), by William G. Spiller, M.D., of Philadelphia; Development of Insane Ideas, by Stewart Paton, M.D., Director of Laboratory Sheppard and Enoch Pratt Hospital; The Sensory Distribution of the Fifth Nerve, by Harvey W. Cushing, M.D., Johns Hopkins Hospital; Amaurotic Family Idiocy, by Bernard Sachs, M.D., of New York; Statistical Data in Paresis, by Edward N. Brush, M.D.; Mechanism of Exophthalmos: Pulse and Blood Pressure Curves in Manic Depressive Insanity, by William B. Cornell, M.D., Clinical Assistant Sheppard and Enoch Pratt Hospital; Spinal Puncture as a Diagnostic Procedure in Paresis, by George E. Chinn, M.D., Clinical Assistant Sheppard and Enoch Pratt Hospital; Delirium Following Operations on the Bile Duct, by J. M. T. Finney, M.D., Johns Hopkins Hospital; Demonstrations of Specimens, by George Streeter, M.D., Johns Hopkins Medical School; Methods of Examination by the Pupil, by Henry M. Thomas, M.D., of Baltimore.

OBITUARY.

Dr. Edward Livingston Trudeau, Jr., son of Dr. Edward L. Trudeau of Saranac Lake, died of pneumonia last Tuesday at his home, 772 Park Avenue. He was thirty-one years old, and was born at Saranac Lake. His academic education was gained at Yale University, where he was graduated in 1896. From Yale he came here to the College of Physicians and Surgeons. Having graduated in 1900, he spent two years in the Presbyterian Hospital, and then started to practice for himself last fall. In December he was married to Miss Hazel Martyn of Chicago. He was a member of the University and Yale Clubs, and attended the clinics of Bellevue and Vanderbilt Hospitals.

Dr. Thomas John Chew, a well-known physician of Washington, died at his home in that city last Monday, in the fifty-eighth year of his age. He was born in St. Mary's county, Maryland, graduated from Princeton and later from the medical school of the University of Maryland. After practising his profession in Prince George County, Maryland, for several years, he moved to Washington.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, April 23.

DEATH OF SIR HENRY THOMPSON—THE PIONEER OF ANTI-VIVISECTION IN ENGLAND—THE PROPHET OF SELF-HELP—THE PASSING OF A FASHIONABLE BONE-SETTER.

The medical profession of this country has lost one of its oldest and most distinguished members in Sir Henry Thompson who died on April 18 in his eighty-fourth year. A few weeks ago I saw him at a leading Club to which he had come to record his vote for a friend whose name had come up for ballot. He looked so feeble as he was helped down the steps and into his motor that it struck me the end was not far off. He was born at Framingham in Sussex in 1820. Of his early years nothing is recorded. There is a legend that he began life as an assistant in a shop. Whether there is any truth in this or not it is certain that he did not take up the study of medicine till comparatively late in life. He studied at University College, London, and took his degree at the age of thirty-two years in 1852 at the same time as his fellow-student, Joseph Lister. He soon afterward married Miss Kate Loder, a well-known pianist, whose earnings smoothed his path to success in his profession. Early in his career he specialized in genito-urinary diseases. He was, I believe, one of the founders of St. Peter's Hospital for Stone, but had to resign his connection with that institution on his appointment to the surgical staff of University College Hospital. He rapidly made his way to the front in his own line, and in 1863 he operated on the late King of the Bel-

gians. This brought him, in addition to a fee of $15,000, the honor of knighthood and a vast increase of practice. In 1872 he operated on the Emperor Napoleon III., but the fatal issue of the case exposed him to severe criticism not only among French surgeons but among his own countrymen. His treatment of stricture in the person of a lord-in-waiting was severely animadverted on by so competent a judge of this branch of surgery as our gracious sovereign Edward VII. In operating Thompson took for his motto Danton's maxim, *de l'audace, toujours de l'audace,* not allowing himself to be deterred by considerations that would have made a careful surgeon stay his hand. Often the event justified his boldness, but sometimes the patient paid the penalty of rash surgery. Then the blame was laid on assistants or nurses. I have seen him perform lithotomy, using considerable violence in extracting the stone, and when post-mortem examination showed that the bladder had been extensively torn, calmly attribute the disaster to an eminent colleague who had held the staff. He was a showy operator, with a shrewd eye for dramatic effect in his entrance, his pose and in his handling of instruments. Within his own province he was for a long time unrivaled in this country. The collection of calculi which he presented to the Royal College of Surgeons bears testimony to the extent of his practice. In general surgery, which his position on the staff of a general hospital obliged him occasionally to undertake, he was somewhat of a terror to his colleagues. It used to be said that he was stopped in the act of attempting to remove the body from a limb, and Berkeley Hill, who had been his pupil, carried with him to the grave the scars of cuts made by Thompson recklessly wielding an amputating knife.

Thompson's professional income was estimated at from $50,000 to $75,000 a year. In his private practice he always operated as early in the morning as possible so that, if bleeding occurred, it might be dealt with in daylight. Probably no surgeon was ever more disliked by his patients. In his later years indeed he would have lost much of his business had he not had the good fortune to have assistants whose devoted attention and charm of manner smoothed away the asperities of their chief. It must be added that Thompson was not popular with his professional brethren. For this his self-assertiveness and combativeness were mainly responsible. There is a curious unconscious revelation of his own character in the novel which he wrote under the name of "Pen Oliver." A medical student calls on an eminent physician to ask for some information not of a professional nature. On leaving he hands the doctor a fee which is accepted as a matter of course!

Thompson dabbled in many things besides surgery. As has just been mentioned he wrote novels of indifferent literary quality. He achieved a respectable mediocrity as an amateur painter, and was frequently allowed to exhibit his works at the Royal Academy. He was a collector of pictures and china. He had an astronomical observatory of his own. He was the author of books on gastronomics and gave dinners called "octaves" because there were eight guests and eight dishes. It is recorded that he once received a visitor in his studio in which he had for companions a young python and a boa constrictor. This recalls Sarah Bernhardt, and indeed Thompson was always a *poseur.* He had enough of the artistic temperament to make him eager to keep himself in the public view and to impress himself on all with whom he came in contact. It must, however, in fairness be acknowledged that he did good work as a social reformer in more than one direction. To him it is mainly owing that cremation has come to be recognized in this country as a lawful mode of disposing of the dead. He was a strong advocate of temperance not only in drinking, but in eating to excess, to which he attributed many of the infirmities that make old age a painful disease to a large number of persons. Within the past year or two he preached the hygienic advantages of automobilism, especially as a remedy for insomnia. Only a few weeks ago he was vigorously denouncing the dirty condition of our London streets and the apathy of our municipal and sanitary authorities with regard to this evil. With all his defects of character, it must be admitted that Sir Henry Thompson was a man of vigorous personality, a leader in his particular province of surgery and a many-sided and accomplished man.

Cremation finds favor with a good many people because it prevents any possibility of premature burial. A notable instance of the haunting fear of this accident is seen in the case of Miss Frances Power Cobbe, well known as an advocate of women's rights and an uncompromising and, it must be added, unscrupulous opponent of vivisection, who died a week or two ago. Her will contained a solemn injunction that her medical attendant should perform "on my body the operation of completely and thoroughly severing the arteries of the neck and windpipe, nearly severing the head altogether, so as to render any revival in the grave absolutely impossible. If this operation be not performed and its completion witnessed by one or the other of my executors and testified by the same, I pronounce all the bequests in this will to be null and void." A letter written by Miss Cobbe to the President of the London Association for the Prevention of Premature Burial, some time ago, shows how great was her fear of being buried alive. She said: "I am obliged to you for sending me 'Perils of Premature Burial.' It is a terrible subject, and one that has haunted me all my life, insomuch that I have never made a will without inserting a clause requiring my throat to be cut before I am put under ground. Of course, one can have no reliance on doctors whatever, and I have myself known a case in which a very eminent one insisted on a coffin being screwed down because the corpse looked so lifelike and full of color that the friends could not help indulging in hopes. My great grandmother, after whom I am called, a famous heiress, was a notable case of narrow escape. As a girl she passed into a state of apparent death, and a great funeral was ordered for her. Among the guests came a young girl friend, who insisted that she was not dead, and raised such a stir that the funeral was postponed, and time was allowed to pass till the marvel became that there were no signs of change. I could never ascertain how long this comatose state lasted before she recovered; but she *did* recover, so thoroughly that after her marriage with Richard Trench, of Garbuly, she became the mother of twenty-two children. Obviously this was no case of a feeble, hysterical, cataleptic subject." Among the well-known people who have been haunted by the fear of premature burial may be mentioned Harriet Martineau who bequeathed her doctor $50 on condition that he saw that her head was amputated before interment; Lady Burton, wife of Richard Burton the explorer, who directed that her heart should be pierced with a needle and her body submitted to post-mortem examination before burial; and Edmund Yates, Editor of the *World,* who left a fee of $100 to his doctor for the same purpose. Miss Cobbe's instructions were carried out by Dr. Hadwen, of Gloucester, a prominent antivivisectionist and antivaccinist. Miss Cobbe was the Cato of the antivivisection cause. Her cry was *Delenda est Carthago,* and she would accept no compromise. This led to a split in the camp, Mr. Stephen Coleridge becoming the leader of a party which professes to aim at the regulation of vivisection, while Miss Cobbe and her intransigent followers insisted on its suppres-

sion. With this object she founded a new society which issued a journal entitled *The Abolitionist*, in which she preached her views with a virulence and scurrility which clearly displayed the cruelty in regard to man that so often underlies the excessive love of animals. She had, however, lost whatever importance she may ever have possessed as a controversialist, since her methods were exposed by Sir Victor Horsley at the Church Congress held at Folkestone twelve years ago.

Samuel Smiles, the author of Self-Help, a book which reckons its sale by millions and which has been translated into nearly every European language, died a few days ago at the patriarchal age of ninety-two years. He began life as a medical practitioner at Haddington, but success not coming speedily enough he became in turn editor, secretary of a railway company, and author of popular biographies of famous engineers and other heroes of practical and business life. His writings have had an immense influence on aspiring young men of the artizan and small tradesman class, but at the present day his teaching, which may be summed up in the phrase, "How to make the best of Both Worlds," has rather lost its hold on the public mind.

English society is mourning the death of a fashionable bone-setter, "Professor" John Washington Atkinson. He knew more of the anatomy of the human body, for he was a qualified veterinary surgeon, and would probably have found it easy to obtain a regular diploma in medicine. But the brain, of what Falstaff calls "this curious-compounded clay, man," being what it is, he doubtless found it more profitable to pose as having knowledge not revealed to orthodox practitioners. He professed to be a specialist in "bloodless surgery" and when Lorenz was over here denounced him in the "society" papers with the fervor of a rival prophet. He had an enormous practice among members of the "upper ten" and had as many as a dozen assistants at work on his patients. Royalty did not disdain to patronize him, and some of the foremost men in the surgical world had to meet him in consultation—of course privily and under seal—under penalty of losing their august patients.

THE NEGRO AS A DISTINCT ETHNIC FACTOR.

To the Editor of the MEDICAL NEWS:

DEAR SIR: There are several important facts belonging to the Negro Question that unfortunately are only well understood by the scientist and physician. Those who have lived among the negroes and studied their inherent race characteristics; and the medical men who have studied the African in the hospital and on the dissecting table, are fairly agreed upon one fact, *i.e.*, that the negro is a distinct ethnic factor in civilization; that his animalism is a biologic factor no more amenable to educational influences than is the biologic origin of his color or odor. The anatomical and physiological conditions of the African must be understood; his place in the anthropological scale realized and his biologic basis accepted as being unchangeable by man before we can scientifically and humanely place this ethnic factor where it belongs. Let it first be understood that there can never be any interracial relations of Caucasian and African, socially or sexually. The African is unlike the Caucasian in *secondary* sexual characters, and this being so he can never be absolutely alike in the highest psychical processes. These facts are ignored by those who would have the African brought into social relations with the white woman, and by those who ignorantly believe that a few years of Latin and Bible teaching will deprive him of periodical erethisms of the sexual centers. When education and religious teachings change the biologic basis of his color it will also be able to change the anatomical and physiological reason for his sexuality and bestiality.

The Caucasian as a race is moral; the African as a distinct race is not immoral, he is unmoral, and no amount of education or training is going to change a non-existing element. This fact should never be lost sight of; it is one of the causes which produce the great psychical differences between the white and colored races. Biologic differences between races of distinct ethnic origin result in psychologic and social differentiation impossible to harmonize.

It is unscientific to attempt to study the adjustment and laws of society without a thorough knowledge of the structure of its individual parts. It is useless for philanthropists, preachers, and editors in the north, or any other part of the country where the African is not understood or studied, to talk about school and college education controlling his hereditary racial instincts. His individual parts are not known to such people. Only he who knows life from the monad to *cell complex man* can intelligently discuss the negro question. To understand the ineradicable racial traits of the African one must know the structural life and habits resulting from a certain biologic basis. We must penetrate beneath superficial ideas, throw aside prudish philosophy, and open our eyes to anatomical and psychical facts if we wish to render justice to civilization. Silence regarding sexual matters must give way to vocative statements; for it is by these unavoidable statements that we must be guided in dealing with the Negro Question.

This great question can only be solved by dealing in concrete facts, not abstract principles; the latter method has been too long in vogue and has resulted in a miserable failure. As an example: The belief that the African was capable of living as hygienically and morally as the Caucasian was the great mistake made by those who deal in abstract principles. Physicians know that this false idea sets in action three of the most powerful enemies of mankind; insanity; tuberculosis and syphilis —diseases which have been so conscientiously studied by the best minds during the last ten years, and whose causes and remedies we are beginning to comprehend. There is every prospect of checking and reducing these diseases in the white race, if this race is socially—in every aspect of the term—quarantined from the African.

It is not necessary here to dwell on the main anatomical points of difference that are known to exist between the Caucasian and the African. These variations show conclusively to the student ineradicable racial traits. The phylogeny of the negro will exert itself under all conditions. Those who would give the African equal social recognition, who sincerely believe that instruction in the humanities will in a few decades bring him to appreciate and understand the ethical and moral code of the Caucasian, forget that centuries of contact with the brain worker has not produced any mental effect in the African beyond those emanating from the medulla. Education as it is understood by the white man will never, in the full-blooded African, affect centers above those governing the animal instincts. It is a fact observed by those who are in a position to study the full-blooded negro that with the advent of puberty all intellectual development ceases; even the "sound memory," which is the cause of much apparent precociousness, seems to be submerged by the growth and activity of sensuality. With the advent of puberty the negro shows his genesic instincts to be the controlling factor of his life. These take hold of religion, control his thoughts, and govern his actions. In the increase of rape on white women we see the explosion of a long train of antecedent preparation. The attacks on defenseless white women are evidences of racial instincts that are about as amena-

ble to ethical culture as is the barrier which keeps the philanthropist and moralist from realizing that the phylogenies of the Caucasian and African races are divergent, almost antithetical; and that it is gross folly to attempt to educate both on the same basis.

William Lee Howard.

SPECIAL ARTICLE.

CYTOTOXINS AND CYTOTOXIC IMMUNITY.*

BY PROFESSOR PAUL EHRLICH, M.D., LL.D.,
OF FRANKFORT-A.-M., GERMANY.

In opening this lecture, Prof. Ehrlich traced the development of our knowledge concerning bacteriolysins and cytolysins and then alluded to the importance of this domain of research. The extent which the subject has attained is shown by the enormous amount of literature which has appeared during the last few years,—in quantity almost too great to master.

The mode of action of amboceptors and complements was first considered. The interpretation of Pfeiffer, Metchnikoff and Bordet's demonstration of the participation of two substances in producing bacteriolysis was made clear by means of absorption experiments and experiments at low temperatures. This led to the establishment of the amboceptor theory. The amboceptor, which is the specific product of immunization, unites by means of one haptophore group with the receptor of the susceptible cell, and by means of another haptophore group, with the complement. The complement has one chemical group suitable for union with the amboceptor, and another, the zymotoxic complex, which causes the injury to the cells. In opposition to this, Bordet devised his theory of "sensitization."

For the theory of direct union, between cell-receptor, amboceptor, and complement, Ehrlich then submitted the following evidence: (1) The demonstration of well-established chemical analogues, as seen in the anilin dyes. (2) The side-tracking of complements by an excess of free amboceptors, as was proved in the case of bacteriolysis by Neisser, and also, firmly established by Morgenroth for hemolysins by the employment of anti-amboceptors. (3) The existence of products from the breaking down of amboceptors,—amboceptoroids, which are no longer anchored by the cell but are still able to divert complements. The amboceptor then really acts like the mordant of a dye. The complete hemolysin thus forms an analogue of a toxin, in which one part, the amboceptor, corresponds to the haptophore group, the second part, the complement, to the toxophore group.

The complement, contrary to the conception of Bordet, is believed by Ehrlich to be made up, not of a single unit, but of a great many partial-complements, which side by side, and simultaneously, become attached to the amboceptor. Accordingly the amboceptor contains a whole series of complementophilic groups, and not a single one, as was first supposed. The diverse amboceptors which can belong to one animal species differ specifically only in those haptophorous groups which are concerned in the union with the cell, while they are identical, or at least very similar, as far as their complex complementophilic component is concerned.

The proof of the multiplicity, as opposed to the unity of the complement can be shown by the method of partial absorption, by the selective destruction of single partial-complements, by the demonstration of anti-complements which inhibit only a certain part of the complement action, and finally, by the evidence brought forward by Metchnikoff, that by the disintegration of microcytes or of macrocytes, at least two complements arise, which differ in their effects, one producing hemolysis, the other, bacteriolysis.

In each individual instance of lytic action it is not necessarily the whole series of complements, but only a certain fraction of them which he termed the dominant complements, that is concerned.

Ehrlich then discussed the theory of amboceptors. The latter are cell products. In the protoplasm of cells, in addition to the simple receptors which give rise to the antitoxins, there are more complicated receptors, which serve in the absorption of the more complex albuminous molecules. Two varieities of these receptors must be distinguished. In the first place, receptors of the second order are those, which in addition to their anchoring haptophore groups, possess a chemical complex which is distinguished by its power to set going coagulative processes, and which is generally quite resistant to heat. As the result of immunization with cells or albuminous material, receptors of this order appear in the serum as coagulins or agglutinins.

In the second place, amboceptors arise from receptors of the third order, which are concerned with the fixation and assimilation of the very largest food molecules. For the catabolic changes of these molecules there are needed a whole sequence of processes, which can only be carried out by a multitude of fermentative agents, such as the complements. Corresponding to this conception, the receptors possess a multitude of complementophilic groups. The reason why these adjuvant groups do not actually occupy the receptors, which would present the simplest solution, may be looked for in their extraordinary lability, which may render necessary a continual rehabilitation and renewal of the fermentative apparatus. This view is favored by the fact that such an arrangement does exist in the case of the receptors of the second order, whose agglutinophore complex, as already mentioned, is relatively stable.

The purpose of protecting these complements from destruction would not be attained if the affinity of the complementophilic groups were such that the complements were continually being absorbed by the receptors. A well adjusted mechanism controls the complement absorption, for by union of the haptophore group with a nutrient molecule, the avidity of the complementophilic group of the receptor is so augmented as to permit its combination with a complement. This is an economy which enables the labile ferment to reach the cell at exactly the favorable moment for its utilization. The proof of the actual occurrence of this increase is furnished by Bordet's phenomenon so-called, in which a selected material, after it is laden with amboceptors, is able to remove complements suitable for itself and also for all other combinations.

Amboceptors can be produced by immunization which are specific antibodies for a great number of albuminous materials, and Ehrlich alluded to the fact that the study of these amboceptors will probably give us a much clearer view than we can now obtain, into the process of assimilation.

We must suppose that those parts of the protoplasm which are bearers of the receptors of the second and third order, must be completely immune to the destructive action of the zymotoxic groups of the complements. There is no direct proof of the partial separation of these particles of protoplasm, yet such a separation probably exists, from the fact that complements are able to destroy their own cells if they are artificially brought into relationship with certain other constituents of the cell. This is effected with extreme ease by the aid of cytotoxic amboceptors, which can be readily produced for all kinds of cells. In this connection he alluded to the

* Third Herter Lecture, delivered at Johns Hopkins University, Medical Department, April 14, 1904.

fact that the erythrocytes of a sheep, which are laden with specific hemolytic amboceptors, will show no signs of injury so long as they are suspended in normal salt solution, but they will be dissolved at once upon the addition of the same serum which was removed from the sheep with the erythrocytes. This demonstrates that the most important agents of the body economy are turned into deadly weapons if brought into a false relation to the protoplasm.

Prof. Ehrlich next considered the theories of the pleuralistic conceptions of cells. Cells are complexly constructed organisms. Each of them possesses an extreme number of separate components, which from a purely theoretical point of view are capable of producing an equal number of specific reaction products. It is probable that each morphologically different cell constituent, such as the protoplasm, nucleus, etc., is capable of producing a serum specifically antagonistic to this particular structure, which serum in turn may be made up of a whole series of partial components.

The number of specific antibodies produced by immunization is usually much smaller than the number of antigenetic substances inoculated. Among the conditions which lead to this result are the deficiency of suitable receptors in the immunized species of animal, and insufficient formation or insufficient shedding of these receptors. He then described the methods for demonstrating the phenomena of pleurality, including the crossed absorption experiments and employment of antiamboceptors, and the examples from hemolysis. An immune serum in the former restricted sense of absolute specificity does not exist, we can only speak of the specificity of one amboceptor type for one definite causative substance. Since the immune sera contain a great number of different fractional components, which in turn can occupy a correspondingly great number of receptors, and since not the whole number of receptors of any one cell are peculiar to this cell, but a variable number of them are also common to other nearly related cells, we must conceive that a serum produced by immunization with a certain type of protoplasm, while it exercises its chief action against this protoplasm, also exhibits its action upon a whole series of other substrata of protoplasm. The more closely related the receptor apparatus of two immunity producing agents is, the more completely do the sera produced by them correspond in their action.

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held January 13, 1904.

The President, William H. Park, M.D., in the Chair.

Blood from Cases of Lymphatic Leucemia.—Mr. L. B. Goldhorn presented a number of specimens of this material. He said that from the hematological point of view, which was the only proper one, lymphatic and myelogenous leucemia could be easily separated, while from the point of view of pathological anatomy such distinctions could not be made. It seemed to the speaker that the myelogenous form was, so to speak, a new growth of those centers of the bone marrow which give origin to the granular leucocytes of the blood, while the lymphatic form was a hyperplasia of those centers which supply the blood stream with lymphocytes. Both types of tissue could form metastases like malignant new growths, the pathological changes in the viscera depending upon them, and just as no two cases of carcinoma with metastases are alike, so no two cases of leucemia are alike. Inasmuch as leucemia is not a disease of the blood proper, it was therefore to be expected that the changes in the blood and plasma would vary as the nature and the seat of the matastases vary. In myelogenous leucemia the speaker was inclined to look upon the mast cells as the only characteristic form, —their enormous increase being so constant a feature that they appear as pathognomonic, for while there are many diseases in which the myelocytes are increased, myelogenous leucemia seemed to be the only one in which these cells were so abundant as to give a characteristic aspect to the blood picture. The speaker suggested for rapid demonstration of this type of cell a saturated solution of a basic dye such as methylene blue or dahlia, in ordinary wood alcohol. The granules are brilliantly stained by applying this solution to the unfixed blood smear for a few seconds, and then washing in distilled water. In what has been termed mixed leucemia an enormous increase in the various granule bearing leucocytes was seen together with what appeared to be large mononuclear cells. This, in the speaker's opinion, was not a leucemia of double, that is, of myelogenous and lymphatic origin, but one of a purely myelogenous source in which the mononuclear cells were not lymphocytes but the mononuclear and transitional cells of Ehrlich. A mixed leucemia would, under these circumstances, appear to be a very rare occurrence, as rare as carcinoma with a sarcomatous element. In determining the hemoglobin in these cases, Mr. Goldhorn recommended the use of the Tallqvist hemoglobin book because its readings were not interfered with by the greatly increased number of leucocytes. He could not recommend this book for general use, because in all cases of lessened oxygenation of the blood, and especially where marked cyanosis was present, the readings were much too high.

Dr. F. C. Wood said that the difficulty of determining the hemoglobin in blood containing a large number of leucocytes could be easily overcome by using the Fleischl-Meischer hemoglobinometer, and after filling the diluting pipette with the blood and distilled water to blow out this mixture into a centrifuge tube and remove the white corpuscle by centrifuging. This would take only a few minutes, and the cells of the hemoglobinometer could be filled with the clear supernatant fluid and an accurate determination easily carried out. If the hemoglobin content were low, a one to one hundred mixture could be made and centrifuged, instead of the usual one to two hundred dilution used for the Fleischl-Meischer apparatus.

Comparative Morphology of Vaccine Bodies.—Dr. James Ewing presented specimens and drawings of vaccinia of the rabbit's cornea, frog's skin and cornea, and mud-puppy's (*Necturus*) skin; diphtherial necroses of the rabbit's cornea, frog's cornea and skin and salamander's skin, and the skin of a case of measles dying in the full eruptive stage of the disease. The specimens were stained by fuchsin and indigo carmine (Borrel's method). In describing the specimens the speaker said in taking up the study of variola in 1901, he had chiefly in mind the hope that the application of Nocht's stain to smear from the lesions of the skin and respiratory mucous membrane might be successful in demonstrating the presence of a protozoon. The results proved negative. Likewise the results of a study of fresh material examined on a warm stage, from variola and vaccinia were negative not only as to the presence of any recognizable protozoon but as well in regard to the question of ameboid motion of any definite structures in the tissues. The histological study of the tissues while defining a great many structures which suggested a protozoon origin had left him as it had previously left the majority of observers, not only in doubt about the origin of many of the suspicious forms, but with the moral cer-

tainty that the morphological study of the vaccine body series in variola and vaccinia could hardly be relied upon to yield positive conclusions even to the most experienced observer, while the type of evidence reasonably demanded to convince others of one's conclusions regarding the nature of these bodies seemed much less likely to be obtainable from this line of study. It seemed possible, however, that the study of changes in the epithelial cells of other classes of animals which might be made to react to vaccine could yield information of value by establishing a comparative morphology of vaccine bodies. The conflicting statements regarding the possibility of producing genuine vaccine bodies by other means than by vaccine also suggested that this subject deserved attention from the same point of view, and would especially assist in separating simple degenerative products from what might prove to be a real protozoon among the host of peculiar structures seen in variolous lesions. With these objects in view he had compared the changes occurring in the epithelial cells in human variola with those occurring after vaccination in the rabbit, frog, mud-puppy (*Necturus*) and salamander, with those resulting from the action of diphtheria toxin, after Sikowsky's suggestion, in the cornea and skin of the rabbit, frog, and mud-puppy, and with those seen in measles. Among the characteristics of the ordinary vaccine body might be mentioned the perinuclear position which is not invariable, the clear zone surrounding the body which is probably an artefact but a very constant one with the larger bodies and the variable staining reaction, some bodies being basophile, others acidophile, many showing both basophile and acidophile portions. The more recently added members of the series, including signet rings, rosettes, crescents, and "encysted" bodies, must be regarded at present as of uncertain relation to the simpler bodies first described by Guarnieri. According to his own observation the most significant features of the ordinary vaccine body is the fact that some are basophile, some acidophile, and others possess both basophile and acidophile portions either compact or granular or vacuolated.

Bodies Produced by Vaccination of the Frog's Skin and Cornea.—Proceeding to a brief description of the bodies observed apart from variola in man or vaccinia of the rabbit's cornea, might be mentioned first the bodies produced by vaccination of the frog's skin and cornea. Here he had more negative than successful results and had inoculated many frogs without any definite effect on the epithelial cells. In the best results a localized lesion of the cornea, and a more diffuse lesion from extensive scarification of the skin were observed. In both locations the bodies were much more numerous than in variola, and included many small acidophile and basophile perinuclear forms, some rings, cysts containing 10 to 50 homogeneous globules or vacuolated bodies or rings. In the frog's skin the specimen exhibited seemed to show rather clearly that many of the bodies had resulted from the comminution of the nucleus Others had a different origin which seemed explicable from the changes produced by diphtheria toxin. In the same locations in the frog diphtheria toxin in twenty-four to forty-eight hours induced cell changes and nuclear and cytoplasmic alterations which seemed to differ from those following vaccination only by their greater intensity. Mechanical influence might have been responsible for some of the changes following vaccination of the frog's skin but not in the cornea, but numerous negative results of vaccination of the frog's skin indicated that the effects of trauma were unimportant. He was inclined to believe that a true progressive vaccine process existed in the skin of the frog in the case exhibited since this lesion was so extensive.

Comparing the lesions produced by diphtheria toxin with those of vaccine in the rabbit's cornea, there appeared many points of similarity and quite as many differences. The toxin failed at least after forty-eight hours to cause the swelling of the cell layer characteristic of vaccine, and the lesion was more intense and the bodies more numerous than with vaccine. Among the changes produced by diphtheria toxin were (1) keratinization of the whole cells or of the whole cell layer, the nuclei staining blue after Borrel's stain; (2) keratinization of cell body alone; (3) keratinization of the perinuclear zone of cytoplasm; (4) separation in globular form of keratin masses which, either in the same or in other cells assumes the perinuclear position and appearance of the vaccine body; (5) transformation of the cell into a cyst containing a great variety of globular, or vacuolated and ring-shaped bodies. Some of these were strikingly geometrical in form and might be described as rosettes. (6) A peculiar series of changes consisted in the formation in the nucleus of one or several large or minute acidophile rings. (7) From the nucleus was sometimes extruded a large strongly acidophile cyst-like body inclosing acidophile granules and minute rings. (8) The peripheral portion of many of the globular bodies broke up into granules which were often regularly arranged in a fringe about a homogeneous central body which was either acidophile or basophile. The fate of all that portion of the nucleus except the nucleolus was a matter of great interest. Careful study of the specimens seemed to demonstrate that the nuclear material apart from the nucleolus did not become incorporated in the fuchsinophile substance but took the form of the basic staining vaccine body. In many nucleoli there appeared a homogeneous basophile substance which sometimes showed convoluted edges, or many regularly placed vacuoles or became broken up into rings. This substance stained brown or blue with Borrel's method, and black after iron-hematoxylin. Very similar vacuolated nuclear bodies were seen in measles. Fuchsinophile intranuclear vacuolated bodies and rings were encountered in diphtherial necroses, and in some foci the changes consisted almost exclusively in the formation of intra- and perinuclear acidophile rings. In variola, especially in the trachea, the multiple nucleoli of the epithelial cells could often be seen to increase in size and to develop several small or large vacuoles, and to appear as congeries of rings. In general it could be said that while diphtheria toxin does not reproduce the corneal lesion of vaccinia it produced definitely many of the typical forms of true vaccine bodies.

In the rabbit's trachea diphtheria toxin produced a great variety of spheroidal or ring-shaped, or vacuolated intracellular bodies, many of which resembled the bodies seen in the human trachea in variola. In the rabbit's bladder, diphtheria toxin produced the usual changes in the epithelial cells, and here many red blood cells had been extravasated into the epithelial layer, fragmented, and lodged between the epithelial cells or about their nuclei. In the mud-puppy (*Necturus*) the inoculation with vaccine in the skin and cornea produced a good deal of keratinization of cells. This formation of homogeneous asidophile material could be seen very definitely in the very large cells of this animal as beginning in the cytoplasm near the nucleus and forming an isolated perinuclear mass resembling a huge vaccine body. Yet the resemblance to the vaccine bodies of the rabbit was extremely distant on account of the large size of the cells. The nucleous and body of the pigmented cell of the skin in necturus frequently became fused into a homogeneous mass and assumed a perinuclear position in other cells. Changes in the nucleoli were not ob-

served in *Necturus*. Inoculation of the skin of the salamander produced much the same lesions as in the frog, but the bodies were much larger and much difficulty was experienced in distinguishing the globules derived from epithelial cells from fragments of red blood cells.

Measles.—In the skin of a case of measles dying in the full eruptive stage of the disease, the epithelial cells in numerous marked foci and diffusely, were found to contain a great variety of intracellular bodies many of which were identical in appearance with the bodies in variola. In certain foci these bodies were much more numerous than he had ever seen in variola. They presented a greater variety of form, and the same variation between acidophile and basophile staining tendency. Keratinization of complete cells and fragmentation of these cells was frequently encountered. Indeed the whole process seemed to be a part of the hyperkeratosis which produced the large flakes thrown off in desquamation in this disease. Among the separate bodies were some which might be described as rings, basophile crescents with acidophile nuclei, vacuolated crescents, pyramidal bodies capping cell nuclei, large basophile or acidophile bodies with vacuoles symmetrically arranged, and many other forms shown in the colored sketch. He could find no satisfactory evidence that these bodies had any other origin than from the epithelial cell bodies and nuclei. After Borrel's stain, the resemblance of these bodies to those produced by diphtheria toxin, or to those seen in variola appeared to be distinct. The acidophile forms seemed traceable to nucleoli and keratinized cell bodies, and the basic bodies, blue and brown, appeared to come from the basophile elements of the nuclei. Nevertheless the resemblance of many of these bodies to developmental forms of a hypothetical protozoon was admittedly great. The occurrence of keratinized cells in the epithelial layer had been described and depicted especially by Bosc in variola and *clavelée* (Cent. f. Bact., Bd. 34, p. 413). This observer correctly stated that whole keratinized cells were readily separated from the "infected" cells in these lesions, but he did not appear to have considered the possibility that these cells might become fragmented and the fragments englobed by healthy cells. Many of the parasitic forms appearing in his sketches were definitely reproduced in the lesions caused by diphtheria toxin.

Anna Foa had recently reported (Archives de Parasitologie T. VII, p. 508) that the bodies produced by diphtheria toxin did not resemble true vaccine bodies which, however, she believed to be degenerative products. No details of this failure to verify Sikowsky's results were given and this part of her extensive study of vaccine bodies did not appear to have been regarded as of much importance.

Summary.—The conclusions drawn from this study were as follows: The inoculation of vaccine and diphtheria toxin in various animals produces a peculiar form of coagulation-necrosis, or keratin necrosis which has been imperfectly recognized and understood, and which results in the formation of homogeneous acidophile material that may be drawn out into fibrils, or broken up into globules, or granules, vacuolated, and englobed by the more healthy epithelial cells in which it appears in the positions occupied by vaccine bodies. This type of necrosis occurs in variola and measles and the bodies produced by it are abundantly present in the epithelial lesions of these diseases. Some of these bodies have been included in the cycles of hypothetical protozoa described by many authors in variola. While forms of a true protozoon may be mixed up with these degenerative products in variola and measles, he was unable to convince himself that any such theory was necessary to account for the suspicious bodies. Some of the suspicious bodies in variola he had been unable to find fully paralleled in diphtherial necroses, especially the presence within the nuclear membrane of several distinct rings of considerable size, and he intended to repeat the systematic comparison of variolous and diphtherial lesions before concluding definitely that no protozoon could be demonstrated in variola and measles. He was strongly of the opinion, however, that the intranuclear rings were vacuolated fragments of nucleolar and nuclear material.

Vaccine Bodies in Monkey's Skin.—Dr. A. W. Williams demonstrated (1) vaccine bodies in monkey's skin (prepared by Dr. Flournoy); (2) smears from vaccine vesicles (Wright's stain.) Dr. Williams said that the specimens shown by her were labeled in detail and it would not be necessary for her to describe them further. She said that since she had had the privilege of examining carefully Dr. Ewing's interesting specimens of rabbit's corneas showing in the epithelial cells changes due to diphtheria toxin, she was more than ever inclined to think that most of the changes seen in the epithelial cells in the lesions of smallpox and vaccinia are due to degeneration and necrosis of the cell contents.

Smears from Vaccine Vesicles.—The two smears, one from vaccine vesicles, and the other, a control from staphylococcus pustules of the rabbit's skin, were brought to show that both have epithelial cells containing similar vaccine-like bodies and that both have a large number of granules in and between the cells. These granules are eosinophile, basophile and a mixture of both. Some of them show beautiful signet ring shapes. The granules have been studied because of the fact that from rabbits vaccine virus filtered through two thicknesses of the finest filter paper has been obtained an almost clear filtrate which was bacteria-free (according to the usual tests) and in which only small granules were seen, but which produced an abundant typical vaccinia when rubbed on freshly shaved rabbit's skin. It has been impossible, however, so far, to discover characteristic granules, though many smears have been examined. Dr. Field kindly assisted in the preparation and examination of these smears. Among various stains used, Wright's modification of Romanowski's stain was chosen for the demonstration of these smears because it had been used recently so successfully by Wright for staining the intracellular protozoon causing Delhi boil.

Trypanosoma Lewisi.—Wright's method was also used for the stained specimen of *Trypanosoma Lewisi* which was demonstrated by Dr. Williams. Dr. Williams thought this *Trypanosoma* might be of interest because it came from one of Novy and MacNeil's test tube cultures, the first pure cultures of a protozoon which have been obtained on artificial culture media. The specimen given to Dr. Park by Dr. Novy about two weeks ago was inoculated into the peritoneal cavity of a while rat; the rat was killed on the eleventh day following, and from its heart-blood were made the two specimens shown, one a hanging drop and the other a dried film. The *Trypanosoma Lewisi* is a flagellate formed frequently in the blood of rats, but seldom causing the death of the animal. This flagellate is also of interest from the fact that it is very similar to the *Trypanosoma Brucii*, the cause of the fatal nagana or tsetse-fly disease of horses in West Africa, and the *Trypanosoma Evansi*, the cause of surra a similar disease met with in India. Since 1901 a number of cases of human infection by an apparently distinct species of *Trypanosoma* have been reported.

Dysentery Bacilli.—Drs. William H. Park and Katherine R. Collins presented a paper on the subject of the dysentery bacilli grouped according to their agglutinins with sera rendered specific by the elimination of the less specific group of agglutinins through absorp-

tion. Dr. Park said his reason for again bringing the subject of agglutination in connection with the dysentery bacilli before the Society was because recent results which they had obtained from the saturation with various bacilli of sera obtained from rabbits previously treated with injections of different strains of dysentery bacilli, seem to be of considerable interest. As is now generally known, the true Shiga dysentery bacilli and those fermenting mannite, although in some sera appearing to agree in their agglutination, yet in others differ almost absolutely. They had previously shown that among the group of the mannite-fermenting varieties there are a number of subgroups, each subgroup containing bacilli obtained from different sources which agree in agglutination characteristics and differ from the bacilli of every other subgroup. The various dysentery bacilli seem especially rich in affinities for such agglutinins as develop through various causes in many adult animals. It is these increased "normal" agglutinins which have caused so much confusion in grouping these bacilli. The blood of a young goat or rabbit which contains no appreciable agglutinin for any of the subgroups becomes, after a single infection with one variety, rich in agglutinin only, for the special bacillus introduced and for others of the same subgroup. Later, after repeated infections the so-called "normal" agglutinins develop, which affect, to a greater or less degree, all varieties of dysentery bacilli. If an animal is injected frequently during a long period of time with a single strain of bacilli, it frequently happens that other distinct varieties of dysentery bacilli are agglutinated in as high dilutions as the variety used for injecting the animals. To prove that such a serum in spite of appearances contained specific agglutinin for the variety inoculated, it was determined to follow the suggestion of Castellani, who separated the common from the specific agglutinins in mixed colon and typhoid infections. It was believed that if the serum from an animal which had been repeatedly injected with one variety of dysentery bacilli was saturated with some other variety the latter might remove all agglutinins for which it had affinity and leave the agglutinins specific for the former. This result was obtained, which permits the hope that in this way a serum truly specific in its agglutination reaction may be obtained for any of the varieties of bacteria comprising large general groups such as those to which the dysentery and colon bacilli belong. The technic was as follows: The surface of the slanted nutrient agar contained in six tubes was inoculated with a single type of dysentery bacilli and the culture allowed to grow for forty-eight hours. The bacilli were then washed off into 90 c.c. of a bouillon culture of twenty-four hours' growth of the same bacillus. To this emulsion was added 10 c.c. of the serum from the immunized rabbit, horse or goat. This 10 per cent. solution of the serum containing enormous quantities of the bacilli was then allowed to stand for twenty-four hours at 37° C. The mixture of serum and bacilli was then filtered through a small Berkefeld filter. The first 50 c.c. of the filtrate was thrown away, as a certain portion of any agglutinins which might be present is retained in the filter from the first portion of the filtrate. If the original serum did not agglutinate higher than 1 to 1,500 the above quantity of bacilli usually exhausted all the agglutinins which had any affinity for the bacilli. The tables showed that the dysentery bacilli used, when tested with exhausted sera, could be divided into three large groups and a number of individual varieties. In rabbit serum before the injections were commenced, there was no appreciable agglutinin for any of the varieties tested. After twelve injections of cultures of a bacillus of the mannite-fermenting type "Class B" agglutinins had developed for "Class B" so that a 1 to 600 dilution of the serum gave a complete agglutination, while for "Class A" of the mannite-fermenting type the agglutination took place in dilutions only up to one part to 200 and for the Shiga type no development of agglutinins occurred. When this "B" serum was saturated with either Shiga of "A" bacilli at least one-half of the aglutinin remained for "Class B" bacilli while all the agglutinin disappeared for the others. In the second experiment given the serum of a horse was used which through injections of both Shiga bacilli and mannite fermenting "Class A" bacilli had developed agglutinins for both these varieties so that dilutions of the serum up to 1-1,500 gave a positive reaction. For all other varieties agglutinins were present to a less extent. These group agglutinins acted in dilutions of about 1-600. Through the absorption of the agglutinins by either of the varieties of bacilli used in injecting the horse all the specific agglutinins for its own class were absorbed together with most of the agglutinins common to most varieties contained in the group of the dysentery bacilli; but the specific agglutinins for the other class largely remained. It will also be noticed that many varieties of bacteria not at all allied to the dysentery bacilli caused more or less absorption of these agglutinins. Others caused almost no absorption. The bacteria which removed agglutinins were all agglutinated in low dilutions by the serum used.

Dr. Ewing said that the examination of Dr. Park's results in the effort to separate the specific agglutinins of very closely related bacterial species, suggested that the absorption method might be employed in the separation of such closely related bloods as human and anthropoid monkey blood by precipitin serum. While he had succeeded with difficulty in identifying higher monkey from human blood by diluted serum, it would seem possible to distinguish more certainly between monkey and human blood or beef, sheep and goat bloods by the use of serum which had been saturated by one of the closely related bloods. After saturation of beef-rabbit serum with sheep blood, only specific precipitin for beef blood ought to remain and none for sheep, but very little would probably be left for either.

Some Observations on the Thread Reaction; its Occurrence in the Human Body.—Dr. E. Libman read a paper with this title. The writer described three forms of specific reactions; the agglutination reaction, the thread reaction; and the so-called "amorphous agglutination reaction." The last having been described by Schmidt during the past year was not discussed by the writer. He said that the subject of the thread reaction was first prominently brought forward by Pfaundler although it had previously been noted by other observers. Pfaundler investigated eight cases of local infection by colon bacilli in each of which he obtained a positive reaction with the serum of the case and the bacillus isolated from the patient in a dilution of at least one to one hundred, if the hanging drop preparations were observed at the end of twenty-four hours. In the febrile cases he obtained a thread reaction, in the other cases a clump reaction. The thread reactions presented the following appearances: The organisms were arranged in long interwoven threads, the latter being generally coiled in skeins. The spaces between the threads were clear and none of the bacilli were motile. Very few individual organisms or single groups of bacilli were found in the thread labyrinths. When observed with high powers the organisms in the threads were of a granular appearance and some were club-shaped. The bacteria could be shown to be alive. In most cases there was more or less agglutination at first. In Pfaundler's experiments he obtained positive reac-

tions only when the patient's blood was tested with the organism causing the infection. He claimed, therefore, that the reaction represented more than a specific reaction; namely, an individualistic one. In some unpublished experiments made by the speaker, in 1898, it was found that the thread reaction was frequently obtained in cases of appendicitis and peritonitis due to the colon bacillus. Only colon bacilli which were closely allied in cultural characters were used. Fever was present in all cases. The general results of the observations were that the thread reactions if they were complete in a dilution of one to twenty seemed to be specific and no interreaction between the various bacilli and a given serum could be demonstrated. The experiments were too few in number, however, to prove distinctly the absence of any interaction and in some cases of proteus infection such interactions were found. In some of the cases agglutination reactions only were present. In a paracolon case described by the speaker two years previous he found that the reaction of the serum with the bacillus always took the form of a thread reaction and that in that case the reaction was distinctly individualistic and assumed a general form resembling chains of streptococci. If agglutination reactions alone had been tested no specific reaction would have been found in this case. The same serum with the same organism no longer gave the thread reaction when transplanted for a number of days on artificial media. This seemed to indicate that the loss of the reaction was due to the change in the bacillus not to a loss of power of the serum. Flexner, Kruse, Duval and Vedder have noted the occurrence of the thread reactions in dysentery and have regarded it as of the same significance as the agglutination reaction. The speaker had found that he could distinguish two forms of thread reaction, one in which the bacilli grew out in long convoluted threads which generally retain their bacillary form. This could be called the end to end reaction and its specific nature is somewhat in doubt. In the other form of thread reaction the organisms assume a coccoid form and the chains resemble those of streptococci. This reaction, in the speaker's experience, when complete was usually specific and individualistic under certain conditions. The reactions are best obtained by making an emulsion in bouillon from a culture of the organism on agar. The suspension must be very dilute, just enough of the culture being used to cause a distinct cloudiness. Sugar bouillon cultures should never be used as in them bacilli of the colon group are apt to take on a coccoid form. In a case of carcinoma of the duodenum with obstruction of the common bile duct the thread reaction was found to occur in the gall-bladder during life. The contents of the bladder was clear fluid, without bile pigment, and contained a small amount of white granular matter. On examining this under the microscope convoluted chains that seemed to be streptococci were found. The sediment decolorized with the Gram stain and the culture made from the fluid gave an organism culturally and morphologically similar to the dysentery bacillus. The serum of the patient gave a chain reaction in a dilution of one to one thousand but no reactions with the colon, typhoid, or paracolon bacilli. The observations made in the case which he had described could not, Dr. Libman believed, be traced to purely accidental influences, nor did he believe they could be due to the icteric condition of the serum, for in the gall-bladder itself the fluid was perfectly clear and not bile stained, and in the second place the serum did not produce such changes in cultures of other closely related bacillary forms. The reaction, Dr. Libman thought, must be regarded as a specific one due to the inflammation of the gall-bladder by the bacillus in question. The observations recorded were of a certain degree of importance because they indicate that great care must be taken in making a diagnosis of streptococci in hanging drops; it must be remembered that one may be dealing with the coccoid forms of bacilli. Dr. Libman had found in a number of instances; in the urine, long chains of what appeared to be streptococci, but on careful examination had been found to be the coccoid forms of the colon bacilli or other bacilli. In these cases it was probable that the acidity of the urine had much to do with the development of the coccoid forms. The difficulty could be avoided, at least to a great extent, by the use of the Gram stain, because up to the present time the thread reaction had been particularly noted with organisms that react negatively to the Gram procedure. In applying the Gram stain on urinary sediments it was important to remember that with very acid urines organisms which are naturally Gram-positive can be very easily decolorized.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section on Clinical Medicine.

Stated Meeting, held April 1, 1904.

Discussion of Appendicitis.—The meeting was devoted to this topic, Dr. Hemmeter treating the medical side of the question. He first referred to the fact that the truth about appendicitis had been learned largely by American surgeons, and he quoted several very flattering foreign opinions of Reginald Fitz. Many fanciful explanations have been advanced to account for appendicitis, Van Cott suggesting that terminal arteries in the appendix may explain the origin of the disease and others explaining it by supposing nerve degenerations to occur. The simplest though probably not the entire etiology consists in the anatomical features of the organ, for we have here a small gut closed at one end. Many cases of appendicitis are catarrhal throughout, and these get well. The two forms which are not surgical at all are catarrhal appendicitis and appendicular colic, the latter being not an inflammation but a muscular effort to get rid of a foreign body. In these cases fever is not present, the swollen appendix can be palpated and the patients recover under medical treatment. In the ulcerated cases, the cases with abscess or obstruction, the fulminating or peracute cases, and the chronic cases treatment is essentially surgical. The Germans, however, aspirate the abscess cases for diagnostic purposes and the subsequent history of some of these, which did not come to operation, shows that abscess absorption is possible. Curiously enough, at the International Congress in Paris, Tuffier and the other surgeons advised conservative treatment in the early stages, while Potain and the clinicians advised surgical treatment. How should we treat a case of appendicitis medically? First, only that food should be given which is absorbed in the intestine, gives sufficient caloric value and does not reach the appendix. A jelly made with Rhine wine answers these demands, and it is particularly important to warn against the use of milk. Secondly, pain must be controlled, and it is best done by morphine in doses too small to destroy tenderness and in that way mask the symptoms. The advisability of rectal feeding is not altogether proven for antiperistalsis undoubtedly occurs, as can be proven experimentally. Fitz and Sahli advise the use of leeches and it is certain that ice-bags externally are of value.

Differential Diagnosis.—Dr. Winslow discussed this phase of the affection, starting from the thesis that appendicitis is in every case a surgical condition. When a patient previously in good health is taken with ab-

dominal pain—often following some indiscretion of diet—fever, vomiting, diarrhea or constipation, we think naturally of appendicitis and the conditions which simulate it. If the case is one of simple colic, temperature is absent, pulse is low, there is no rigidity, the pain is in the small intestines and is relieved by abdominal pressure. The symptoms in this case, so far from increasing, gradually diminish. In gall-stone colic the pain is higher up, the bladder may be palpable under anesthesia and jaundice is in many cases present. Intestinal perforation is often diagnosed from the symptoms previous to the acute attack, and in case of typhoid fever by the Widal reaction. In females the ovaries and tubes have always to be thought of, and in any case of peritonitis the probability is fairly strong that the appendix was the original source of trouble. Enteroptosis is sometimes a confusing condition. Surgical treatment should be instituted immediately, but Ochsner's method may be of value in the late early and in the early late cases.

Pathology of Appendicitis.—Dr. Hirsch discussed the pathology of appendicitis, referring first to anatomical considerations. The appendix appears about the tenth week of fetal life and is in all probability due to retarded development. It is usually situated behind the cecum pointing toward the spleen and the failure of its artery to run as far as its tip may have clinical importance. The predisposing causes to its inflammation are its structure, its short mesentery and possibly the rheumatic diathesis. The exciting causes are foreign bodies and microorganisms. Pins, worms and concretions having been found in about seven per cent. of 14,000 cases analyzed by Mitchell. The colon bacillus, the pyogenic cocci, tubercle bacillus and the actinomyces are the organisms most often found. Pathologically there is only one form of appendicitis, the acute infective type, but the cystic, the parietal, the gangrenous and the perforative form may be distinguished clinically.

Immediate Surgical Intervention.—Dr. Blake favored this mode of procedure when the diagnosis was made, but the difficulty of the diagnosis was illustrated by a case of his who died of multiple liver abscess following appendicitis, her case having been thought to be typhoid fever, tuberculous peritonitis or actinomycosis of the liver.

Dr. Atkinson referred to the value of the leucocyte count in making the diagnosis early, though he admitted that in many cases it was of no help whatever. He also referred to the confusion in diagnosis which may be caused by perinephric abscess and by retroperitoneal glands.

Dr. Watson said that in his experience as a general practitioner he had found it wise to refer cases of appendicitis to a surgeon immediately, and his general rule was always to send his cases when there was increase of any symptom, whether pulse or pain or what not. He had never had any cases operated on too early, but he had several operated on too late. One patient of his was seen in the evening with suspicious but not marked symptoms. He decided to watch the case till morning. She passed an exceedingly good night, sleeping naturally and without pain and was quite comfortable next morning. Her pulse, however, had risen slightly and on that indication she was referred to the surgeons who found an appendix in very bad condition.

Loving Cup for Dr. W. T. Bull.—Dr. William T. Bull severed his connection with the College of Physicians and Surgeons Wednesday, and as a sign of their regard the classes of 1904 and 1905 presented to him a silver loving cup, suitably engraved.

BOOK REVIEWS.

The International Medical Annual. A Year-book of Treatment and Practitioner's Index. 1904. Twenty-second Year. E. B. Treat & Co., New York.

The International Medical Annual is always an excellent review of the past year's medical literature. Its contributors are mainly distinguished English medical men and it is well known how conscientiously they do their work. One of the features of the present year is the introduction of stereoscopic views of pathological specimens. These give an excellent idea of the shape and form of specimens and of the localization of lesions. A little instrument is provided for the examination of the views and there is no doubt that it adds greatly to the solution of the difficult problem of the illustration of pathological conditions. There are some excellent plates in illustration of typical stages of certain of the exanthemata.

As is usually the case, the volume is largely devoted to treatment. Among the reviews of recent literature that seem especially practical are those of diabetes and of drug poisoning. The subject of anesthesia, too, has a very full review, and the recent literature of kidney affections has received the notice that its extensive list deserves.

Infant Feeding in Its Relation to Health and Disease. By Louis Fischer, M.D., Visiting Physician to the Willard Parker and Riverside Hospitals, New York City, etc. Containing 54 Illustrations with 24 Charts and Tables, mostly Original. Third Edition. F. A. Davis Company, Philadelphia.

This excellent book seemed perfect before and yet the author has found means of improving it. In this new edition very considerable changes have been made, some of the old matter being omitted and several new chapters added.

One of the most timely of the additions is a chapter on "Buttermilk Feeding," which has lately been attracting much attention abroad. The food is prepared by adding flour and sugar and boiling; it has many advantages over other forms of artificial food owing largely to the strong bactericidal powers possessed by buttermilk. Another valuable addition is the chapter "Milk Idiosyncrasies in Children," in which the trying cases of children who will not tolerate milk are discussed. A chapter on feeding children with cleft palate has also been added.

The problem of adapting artificial foods to the individual needs of infants is becoming so vital that no practitioner can afford to neglect this rather difficult branch of treatment. Every one, experienced or tyro, will derive the greatest assistance from this book, which is surpassed by none in practicality, convenience of reference and authoritativeness.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

La Rhinoplastie. By Drs. C. H. Nelaton and Ombredanne. 8vo, 438 pages. Illustrated. G. Steinheil, Paris.

Diseases of the Intestines. By Dr. M. Einhorn. Second edition. 397 pages. Illustrated. Wm. Wood & Co., New York.

Commoner Diseases of the Eye. By Drs. C. A. Wood and T. A. Woodruff. 8vo, 500 pages. G. P. Englehard & Co., Chicago.

INTRASPINAL INJECTION OF LYSOL SOLUTION IN THE TREATMENT OF CEREBROSPINAL MENINGITIS, WITH A REPORT OF THREE CASES.*

BY MORRIS MANGES, M.D.,

OF NEW YORK;

PROFESSOR OF CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL; VISITING PHYSICIAN TO MT. SINAI HOSPITAL.

THE report of any method of treatment which is based upon only three cases must necessarily be received with a certain amount of reserve; yet, in a disease with so high a mortality rate as cerebrospinal meningitis, the results in these three cases are so striking that I may be pardoned for publishing this method even after so limited an experience.

In this disease the determination of the prognosis in each individual case is exceedingly difficult, in spite of the fact that the mortality rate is so high. The gloominess of the prognosis is due to the poverty of our therapeutic resources. The perusal of the various monographs on the subject shows how very limited is the sphere of our therapeutic agents. How little advance has been made up to recent times is well shown in the article on this subject in Leyden and Goldscheider's classical treatise "Diseases of the Spinal Cord and Medulla."† Councilman, Mallory and Wright, in their report on this disease published in 1898, even after the introduction of lumbar puncture, give an equally discouraging picture. Eichhorst's monograph, written in 1902,‡ the most recent publication on the subject is equally pessimistic.

So far as we have been able to learn from a review of the literature, methods of treatment have but little influence on the mortality, which, for the epidemic form, is estimated from 20 to 75 per cent. While the sporadic form is not so fatal, yet the mortality of all the cases of cerebrospinal meningitis, (including all varieties of bacteriological origin, the meningococcus being present in most cases) is often over 50 per cent. Among the recent methods of treatment may be mentioned prolonged hot baths at 104° F., from the use of which a number of cases of cure have been reported. The results of laminectomy and washing the spinal canal, as done by Osler and others have not been encouraging. The only real advance in therapeutics is the lumbar puncture, performed once or repeated a number of times during the course of the disease, but this alone has cured only a limited number of cases.

We are indebted to Seager for the publication of a new method of treatment, the results of which are most encouraging. His experience is based upon his observations in a series of cases of the epidemic form at Lisbon.*

This treatment consists of lumbar puncture and the withdrawal by aspiration of varying quantities of cerebrospinal fluid from the spinal canal, frequently amounting to 50 c.c. "Artificial serum is then injected with the same syringe, the needle being left *in situ*, and the surrounding parts are washed with serum; lastly, a quantity (from 9 to 12 c.c.) of a one per cent. solution of lysol is injected through the same instrument and the needle withdrawn. The temperature falls immediately, but rises again after one to three days, when the puncture and injections are repeated, and so on until only quite clear and limpid fluid is withdrawn after puncture, when the injection of lysol is stopped. Afterward a few punctures are made to see if the fluid continues clear." Seager calls attention to the painfulness of the treatment, which, however, my own experience in the three cases treated does not corroborate (see addendum).

Of the 31 cases in Lisbon which were treated with lysol, 13 died—5 from dilatation of the cerebral ventricles, 2 from pulmonary tuberculosis, 1 from edema of the glottis, 1 from purulent pneumonia and 4 from the disease without complications. The 18 that recovered were *completely* cured.

The early plan of treatment in this same epidemic was by hot bath and ice-bag to the head. Under this régime 60 per cent. died Then simple lumbar puncture of the spinal canal was tried in 20 cases, in 3 of which the fluid was already purulent. Of these 20 patients 9 died, and of the 11 who recovered, 1 was deaf, 1 had persistent paralysis of the left arm and 4 had bed sores. The next 7 cases were treated with puncture, removal of the fluid and an injection of oxycyanide of mercury. Of these 7 cases 4 died and 3 were cured. The fluid was purulent in 5 of these cases, 4 of which proved fatal.

The number of cases treated by lysol could have been increased had Seager included 20 cases which were under treatment at the time of his report, but inasmuch as the duration of this disease is often long, he did not include those under treatment, although he states that the majority of them were in such good condition that their recovery seemed assured, hence the results of the treatment are even better than 57 per cent. of complete recoveries in the 31 cases noted above. The presence of the meningococcus was the only characteristic bacteriological finding in the cases.

Of the three cases which I report the first was a meningococcus infection and the second a viru-

* Lancet, November 1, 1902.—Seager does not state who first introduced this plan of treatment, but simply reports his observations at the Special Hospital at Lisbon.

lent streptococcus. While it must remain an open question whether the meningococcus case would have recovered without this treatment, since the sporadic cases in adults not infrequently do so, yet the fact remains that the patient was losing ground steadily in spite of the various treatments, including lumbar punctures, which were employed. After the first injection he seemed to hold his own, while following the second his recovery was rapid and uneventful.

Of the second case I can speak with much more assurance, since, at the Mount Sinai Hospital, death has resulted in every case of cerebrospinal meningitis in which the streptococcus was found in the fluid obtained by lumbar puncture. The condition of the child at the time of the first lysol injection was so desperate that no one who saw the case expected him to survive the night, hence his complete recovery without any after-effects is all the more gratifying. It is to be noted that the washing out of the spinal canal with artificial serum was omitted in all of these patients. The injections were all made without anesthesia, except the first one in the child, which was done under slight chloroform narcosis. No pain was complained of and no unpleasant after-effects were noted.

At the present writing all of the patients are perfectly well. The details of the histories, for which I am indebted to Doctors Oppenheimer and Ziegel, of the House Staff, are as follows:

Case I.—J. R., thirty-three years of age, Austrian, tailor, admitted to the Mount Sinai Hospital January 30, 1904. Family and previous history negative in all respects except an uncomplicated attack of measles as a child. Present illness began abruptly six weeks before admission with chill, headache, general bodily pains and fever. The headache, fever and prostration continued for about two weeks when the patient was able to be up. He then had another chill and the headache returned. Stiffness of the neck was complained of and he has since been in bed. He has been vomiting for the past four days, three or four times daily, not projectile. Slight cough and mucopurulent expectoration. Constipation has been a prominent symptom throughout. Urination is very painful and the total quantity is diminished. No herpes. Considerable loss of flesh and strength. Severe headache has prevented sleep, but the mental condition has been soporose.

The main points in the physical examination are as follows: Patient lying on the side with extremities and body flexed, but the head somewhat extended. Considerable rigidity of the neck. Tenderness on percussion of the skull. Some photophobia, pupils markedly contracted, equal, react to light and accommodation; no strabismus. No facial paresis. Ears negative. Tongue is very dry. Marked *tâche cérébrale*. A few small, faint roseolæ on the abdomen. No general hyperesthesia. Abdomen retracted and tender on deep palpation. Tendon reflex somewhat diminished. Kernig's symptom somewhat marked but neither McEwen's nor Babinski's sign. Otherwise the physical examination was negative. Rectal temperature on admission 100.4° F.; pulse 46; respiration 18. *Urine:* Sp. gr., 1.020, total quantity 37 ounces. Faint trace of albumin, no sugar, 2.5 per cent. urea, a few hyaline casts and blood cells. Negative Diazo. White cells 23,000. Negative Widal.

The following day temperature rose to 101° F. in the evening. Pulse ranged between 54 and 66; respiration 18 to 20. Two counts of white cells showed 14,000 in one, 15,000 in the other.

February 1.—Since admission patient has continued to have severe headache with marked tenderness on percussion of the left side of the head. No vomiting since admission. Blood culture by Dr. Libman negative. Patient is mentally clear, but has a dull, apathetic expression. Rigidity of the neck marked. Still very much constipated, cathartics ineffectual. The left knee-jerk more active than the right.

February 2.—Temperature almost normal. Pulse ranged between 50 and 80; respiration 20 to 26. Lumbar puncture yielded 6 c.c. of somewhat turbid fluid which was obtained drop by drop (no pressure). Following lumbar puncture there was no increase of headache. Examination of the eyes by Dr. Gruening was absolutely negative.

February 3.—A few moist râles at the right apex. Two examinations of the sputum yielded no tubercle bacilli.

February 4.—Patient has improved somewhat; slight headache. Slept well. Rigidity of the neck the same. The tâche and the Kernig are still well marked.

February 6.—Recurrence of headache which is now more severe and general—worse on the left side. Tongue very dry and deviates to the left. No facial paresis. Pulse 66 to 68. Second lumbar puncture yielded 3 c.c. of turbid fluid the same as that obtained at the first tapping. Dr. Libman reports that meningococci are present in both specimens; polynuclear cells predominate. Percentage of albumin markedly increased; no reduction of Fehling's solution.

February 7.—The patient complained of severe headache immediately after lumbar puncture; but on the following day he complained much less of it.

February 10.—Yesterday afternoon after seeing visitors patient became stuporous and later almost comatose, with involuntary urination and defecation. Pulse 48 this morning. Takes nourishment with difficulty. Too weak to move in bed. Was given a hot bath at 104° F.

February 12.—Mental condition about the same—very apathetic. Feeding is difficult. Rigidity of the neck is undiminished. Tâche still present; knee-jerks absent. Kernig still present, but less marked. No Babinski or McEwen. Pupils equal, although yesterday the right was larger than the left. No paresis. Fundi negative. Hearing in both sides normal.

February 13.—General condition somewhat worse than on the preceding day and the patient lying on his side curled up in bed with rigid extended neck, almost comatose, in decidedly worse condition than at any time in spite of all treatment, which included prolonged hot baths at 104° F., iodides, ergot, etc. Having decided to use the lysol injection, a lumbar puncture was made and 12½ c.c. of slightly turbid fluid were withdrawn by means of aspirating syringe attached to canula; 9.5 c.c. of sterile one per cent. lysol solution were injected through the canula into the spinal canal, nine minutes being required for the injection. During and immediately after the injection patient was comfortable and no untoward symptoms followed the injection.

February 14.—Patient is just as apathetic as before but does not complain of headache. Pupils are very unequal, the left being larger than the right, but they react to light and accommodation. The pulse is normal but the respiration is slow and somewhat irregular. No knee-jerk obtainable. Rigidity of the neck about the same. Tâche less marked; hypotonia of the muscles.

February 15.—He is decidedly better. Much less apathetic; slight headache only. Rigidity of the neck slightly diminished. Knee-jerks still absent; Kernig and tâche still present. Patient takes nourishment better; has no difficulty in swallowing. He looks brighter.

February 16.—Lumbar puncture attempted, no fluid obtained, but as the needle seemed to be in the spinal canal 10 c.c. of one per cent. lysol solution were slowly injected.

February 17.—Patient improving; no headache. Takes nourishment and sits up. Other signs same as noted. Knee-jerk still absent.

February 18.—Improvement continues. Out of bed. Can now touch chin to sternum.

February 21.—Walks about the ward. No symptoms complained of. No rigidity of the neck. Left pupil still larger than the right. Slight tâche appears very slowly. Knee-jerk obtainable on the left side, not on the right. Kernig's sign still fairly well marked. Pulse 88 to 92; respiration 20. Temperature normal, as it has been practically since February 8.

February 23.—Patient apparently well. Knee-jerks returned. No rigidity of the neck. Pupils equal.

February 26.—Patient discharged cured.

Case II.—Walter A., born in the United States, ten years of age, admitted February 23, 1904, to Mount Sinai Hospital, service of Dr. Sachs, to whose courtesy I am indebted for the privilege of reporting this case. The previous history of this patient will be found in Dr. Gruening's article in the Jacobi Festschrift (1900) entitled "A Case of Otitic Brain Abscess in a Boy Five Years of Age." This history in brief includes an attack of otitis, mastoiditis and brain abscess five years ago for which he was operated upon by Dr. Gruening. The pus from the brain abscess showed streptococci. The boy was discharged cured five weeks after the operation. During the past five years the patient has been absolutely well with the exception of an attack of measles two years ago. There has been no discharge from the ear. The boy was very bright mentally and there were evidently no sequelæ to his otitic brain abscess except loss of hearing on the right side.

Present Illness.—Four days before admission there was a sudden discharge of a large quantity of clear watery fluid from the right ear. Up to to-day there has been no pain, fever or constitutional disturbance. At 4 A.M. to-day there was again a profuse serous discharge from the right ear, the patient complaining of agonizing headache and bursting pain in the right ear. Temperature 104° F. He had a slight convulsion and vomited four or five times. Since this morning he has been stuporous with occasional attacks of restlessness. He is unable to urinate voluntarily.

Examination on Admission, February 23, 1904.—Patient semi-comatose, aroused with difficulty, unable to answer questions or recognize his surroundings. Lies fully flexed with retracted head and rigid neck. Photophobia; some injection of the conjunctivæ. Pupils are equal, moderately dilated and react normally. Left ear is negative. Right ear shows scar of previous operation in right mastoid region; there is tenderness. Profuse serous discharge from the right ear. Tongue moist and coated. Throat negative. Slight glandular enlargement in the anterior cervical and inguinal regions. No McEwen's sign; no *tâche cérébrale*. The respirations are very shallow, rapid (60) and irregular. Heart and lungs negative. Abdomen retracted, generally tympanitic. Liver and spleen negative. Knee-jerks diminished but present. Kernig's symptom present. No Babinski; no clonus. On admission temperature 105° F., pulse 104, respiration 60. White blood cells 22,400.

He was seen by Drs. Gruening and Sachs, the latter advising lumbar puncture, which was immediately performed by Dr. Lilienthal; 10 c.c. of very cloudy cerebrospinal fluid were withdrawn, the fluid being apparently under pressure.

Dr. Libman reports as follows: On standing three-eighths inch purulent deposit. *Cytology.*—Nearly all the cells are polynuclear. Streptococci found in pure culture in spreads and cultures. Albumin markedly increased; no sugar reaction. There was no apparent change in the patient's condition after puncture.

At this time, having been asked to see the case by Dr. R. Abrahams and Dr. Gruening, I advised the use of the lysol injection. Four hours after the first lumbar puncture the second lumbar puncture was made, 9 c.c. of purulent fluid being withdrawn. Dr. Libman's report on this was the same as that on the first, with the exception that the fluid was more cloudy and contained more streptococci. Following the withdrawal of the fluid, 6 c.c. of sterile one per cent. lysol solution were slowly injected through the canula of the lumbar puncture needle.

The patient's condition at the time of the in-

jection may best be inferred from the fact that none of us expected to see him alive on the following morning. During the night, the child, who had previously been stuporous, became very restless and had three general convulsions each lasting a few minutes. Digitalis and bromides were given, also nutritive enemata, since he was unable to take nourishment. On the following morning the temperature dropped to 101° F. He was able to urinate voluntarily.

February 24.—The patient is somewhat improved. Mental condition is soporose with intervals of restlessness. Pupils are equal and contracted. Knee-jerks not obtainable. Kernig's sign is present; no McEwen or Babinski. *Tâche cérébrale* now present. Patient must be catheterized every six hours. Urine, sp. gr. 1.010, trace of albumin; no sugar. Temperature 101° F. Pulse 108, fair quality. Respiration 52, shallow and irregular. Defecation involuntary. The discharge of serous fluid from the ear continues. Examination of the ear by Dr. Gruening shows the presence of a pedunculated mass covered with skin which almost completely occludes the external auditory canal and prevents inspection of the deeper parts. Four P.M. Lumbar puncture. Five c.c. of turbid fluid withdrawn. Dr. Libman's report the same as yesterday except that the streptococci grow much more slowly. A second lysol injection of 8 c.c. of a sterile one per cent. solution was given after the withdrawal of the fluid.

February 25.—Decided improvement in the patient's condition. Nourishment is being taken by mouth. The boy talks at times, though somewhat irrationally; is irritable on being disturbed. Meningeal signs are still present though less marked than yesterday. Temperature 101° to 102° F. Pulse 94, fair quality, slightly irregular. Respiration 30. Involuntary defecation still continues. Urine must still be withdrawn by catheter. Treatment: 2 grains of urotropin b.i.d., sodium bromide 3 grains q. 3 h., fl. ext. digitalis 1 m. t.i.d. Discharge from the ear continues free. Examination of the right fundus shows sharp outline of the disk with veins apparently congested.

February 26.—Improvement continues; patient is perfectly conscious and talks rationally. Complains of diplopia; no objective eye symptoms. No paresis of face or extremities. Knee-jerks have returned; Kernig's sign still present. No tâche. Takes considerable nourishment. Temperature 100.2° F.; pulse 100; respiration 30. Urination is now voluntary. Discharge from the ear as before.

February 27.—Recurrence of headache and stuporous mental condition. Lumbar puncture was repeated, 16 c.c. of clear fluid being obtained. No lysol was injected because the fluid was clear. Dr. Libman reports no bacteria in the smear; no growth in the culture. Culture of discharge from the ear shows numerous streptococci.

February 29.—Though the temperature still ranges from 101° to 103° F. the patient's general condition continues to improve. He is perfectly rational, takes plenty of nourishment, defecates and urinates voluntarily. The only meningeal symptoms which persist are moderate rigidity of the neck and Kernig's sign. Discharge from the ear continues. Culture from the urine shows no streptococci.

March 1.—Temperature 100° to 101° F. Pulse is now regular; respiration no longer rapid, shallow or irregular. Knee-jerks are obtained; Kernig's sign persists, also some rigidity of the neck.

March 2.—Discharge has ceased. Temperature, respiration and pulse normal. Patient looks and acts like a perfectly healthy boy.

March 6.—Out of bed. Perfectly well.

For the details of the *third case* I am indebted to Dr. Seff, of the House Staff of Mount Sinai Hospital. While on his vacation visit to his home in Northumberland, Pa., he was asked by Dr. C. Rutter to see a very severe case of cerebrospinal meningitis. The patient was a boy, six years old, who had had no illness except measles, some years ago. Family history non-tuberculous. An older sister had just recovered from an attack of cerobrospinal meningitis of four weeks' duration.

On March 3, 1904, he became restless and irritable. *March 4.*—At 4 P.M. had severe chill, followed by fever (103.2° F., mouth), pulse 114, respiration 36. Soon the child became stuporus, and rigidity gradually developed. Vomiting was frequent. Examination was negative, excepting the absence of tendon reflexes. During the night, opisthotonos developed. This condition of marked irritability on arousing him, moderate fever, rapid and irregular respirations, pulse about 100, opisthotonos, etc., persisted, and this was the condition when Dr. Seff saw him on March 7. A distressing feature, in addition, was a very marked tympanitic distention of the abdomen. The entire body was covered with a fine papular, vesicular rash. Dr. Seff, knowing the good results in the two cases reported above, advised lumbar puncture and lysol injections. At 11 P.M. 5 c.c. purulent cerebrospinal fluid were withdrawn and 4 c.c. of a one per cent. sterile lysol solution were injected. Almost immediately there was a very abundant discharge of flatus with relief of the abdominal distention, although high enemata of various kinds had failed to relieve it. The night was uneventful; but on the following morning (March 8) the stupor was not so profound, the pulse was of better quality (104), respirations regular, fever 101° F.; the child seemed better in every way and the opisthotonos had disappeared.

March 9.—Child absolutely rational; reflexes have returned; some rigidity still present. Takes food readily.

March 12.—Child is practically well; is on soft diet. Unfortunately no cultures could be made, as Dr. Seff was unprepared for any such emergency.

In conclusion, I would state that I present the

results of these three cases with all the reserve which must necessarily be associated with so limited an experience. Only a more extended trial will enable us to determine whether equally satisfactory results will be obtained in a larger number of cases. It is to be noted that these observations corroborate the results obtained at Lisbon; they are far better than any results which have followed the varied plans of treatment in the severer cases at Mount Sinai Hospital. Furthermore, the treatment is harmless and involves as little risk as does lumbar puncture.

ADDENDUM.—Since the above was read on March 15, 1904, through the courtesy of Dr. B. Oppenheimer, House Surgeon at Mt. Sinai Hospital, I have received a copy of the original Portuguese monograph by Carlos França, "Meningite cerebro-espinhal epidemica," Lisbon, 1903. This essay, which is a very elaborate report on 103 cases of the disease observed in Lisbon, was unfortunately received too late to permit any extended reference while correcting proof sheets, but will be discussed elsewhere. Suffice it to say that as the result of his experience with the very fatal epidemic at Lisbon, França is very hopeful as to the results of the lysol treatment. He is emphatic in asserting that in many cases lumbar puncture alone will not cure severe cases.

The washing of the canal with artificial serum (normal saline solution) was used only in a few cases where the cerebrospinal fluid was very tenacious. This procedure is improperly described by Seager. This method consists in inserting a second canula between the twelfth dorsal and first lumbar vertebræ and injecting the artificial serum with a syringe through the upper canula and allowing it to escape through the lower; this being done until the fluid contains only a few flocculi.

The quantity of lysol solution injected is 3 to 9 c.c. for children and 12 to 15 c.c. for adults. The injections are made daily till the fluid is clear. If there is much hyperesthesia, or if the patient is very rigid, a short chloroform narcosis is advisable.

My subsequent experiences with the lysol treatment will be detailed later. Suffice it to say here that the results thus far obtained more than justify its employment in the severer cases.

Glycogen Reaction of Leucocytes in Tuberculosis.—G. SCHRÖDER (Münch. med. Woch., March 15, 1904) draws attention to the fact that the presence of pyogenic organisms in the sputum of tuberculous patients does not necessarily mean that these germs participate in the process, as they may also occur as harmless saprophytes. Since fresh blood-specimens when treated with a solution of iodine and potassium iodide in gum arabic will give evidence of granules of glycogen in the leucocytes in cases of sepsis and suppuration, it seemed proper to test the blood of consumptives in the same way in the hope of disclosing secondary infection. Twenty-two cases of advanced tuberculosis were tested, but a faintly positive reaction was obtained in only two where true abscesses were present. The intracellular glycogen reaction is thus of no value in tuberculosis.

A CASE OF CARCINOMA OF RETAINED TESTIS.*

BY SINCLAIR TOUSEY, A.M., M.D.,
OF NEW YORK.

THE case which I am about to report was referred to me by Drs. Douglas H. Stewart and Robert Coleman Kemp, and was also seen by Dr. Ferd. Valentine and Dr. T. M. Townsend. It is one of carcinoma of a retained testis, forming a tumor occupying a large part of the abdomen; removal by laparotomy, rapid recovery; evidences of recurrence within two months, and death in about six months; the autopsy showing a carcinomatous mass extending from the third lumbar vertebra to the level of the second rib, and including the aorta and vena cava.

The patient, F. M. F., a musician, was a man, thirty-three years old, with both tuberculosis and cancer in his family history. He was born with a number of malformations, which were attributed to maternal impressions. Among these were claw-like deformities of the hands and feet, some of the phalanges being absent. Both testes were completely within the abdominal cavity and neither could be felt. There was an inguinal hernia; and an exaggerated hypospadias with apparent absence of the penis. The penis was buried in a sulcus which appeared like a vulva, the glans pointing back toward the anus. There was practically no corpus spongiosum, and the whole external genital region was almost as smooth as the palm of the hand, with the urethra hardly to be discovered.

Dr. Stewart operated for this condition in March, 1887, and manufactured a penis of very presentable appearance, and the patient assured us that satisfactory intercourse was accomplished whenever he so desired. This newly formed penis contained no urethra. The operation consisted in dissecting out the penis and doing some plastic work and skin-grafting, and was remarkably successful.

In January, 1899, the patient began to have fainting spells, with pain in the lumbar region; and in 1900 convulsions at night, occurring after physical overwork or exposure. In April, 1902, there was an attack of intense pain in the small of the back which was supposed to be of a rheumatic, neuralgic or tuberculous origin and which continued up to March, 1903, when Dr. Stewart was called to see the patient for the first time in a number of years. The condition then found was one of enormous swelling of the colon, forming a genuine enteroptosis. The patient was referred to Dr. Robert Coleman Kemp, at St. Bartholomew's Clinic. Dr. Kemp applied a Rose's belt, which in forty-eight hours, reduced the swelling to such an extent that the tumor could be felt, and the case was then placed in my hands.

At the time that this patient came to me he was moderately emaciated and presented a tumor occupying the entire lower portion of the abdomen from two inches above the umbilicus. This

* Report read and specimens and photos shown at a meeting of the Genito-urinary Section of the Academy of Medicine, January 20, 1904.

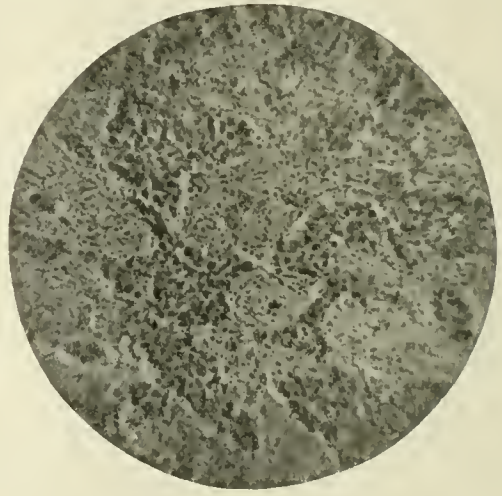
felt softer and cystic on the right side. A fluoroscopic X-ray examination was made, but did not assist in the diagnosis, which was that of tumor of retained testis. We were unable to determine before the operation whether it was of the right or left testis or of both. There was also a right inguinal hernia with considerable thinning of the tissues over it by the prolonged pressure of a truss. Neither testis could be found in the scrotum, groin, or abdomen, and the supposition was that one of them formed the tumor which nearly filled the abdomen. There was very severe pain in the region of the second lumbar vertebra, which made it very difficult for him to lie down at all.

On March 27, 1903, I operated at St. Mark's Hospital, ether being the anesthetic used. An incision was made in the median line from a little above the umbilicus to the pubes, and through this large incision nothing but tumor could be seen or felt. There were a few feathery adhesions between the tumor and the anterior abdominal wall, and on breaking these up it became evident that the tumor was retroperitoneal with a broad base about nine inches in diameter, and that its anterior surface, in contact with the anterior abdominal wall, consisted of the posterior peritoneal coat of the abdomen, which had been gradually lifted forward as the tumor developed behind it.

At first, the appearance of the tumor was that of a fibroid uterus, but later, as the peritoneal investment was cut away at the circumference and the growth was separated from the anterior abdominal wall, a portion of it was found to be a cyst, through the transparent wall of which could be seen about two pints of a clear yellow liquid. The location of this cyst and the appearance of its contents were so peculiar as to elicit a word of caution from one of the surgeons present in the form of the question "Where is his bladder?" A digital prolongation from this cyst extended down into the hernial sac. The cyst and the solid portion of the tumor were inseparably connected, and the entire mass was removed without rupturing the sac. This required only blunt dissection posteriorly, and the only large vessels encountered formed a broad band entering the peritoneal coat from above. The solid portion of the tumor, which I show here, weighed about four pounds, and on microscopical examination proved to be carcinoma with a considerable amount of soft fibrous tissue. None of the normal structure of the testis could be distinguished microscopically.

The patient made a rapid recovery, but in a couple of months a mass could be felt in the upper part of the abdomen a little to the right of the middle line. This at first gave him no trouble and he spent a few months as the musician at a summer hotel. The pain in the back returned, however, and finally became so severe as to cause him to return to the city, where he died on September 11, 1903, about five and a half months after the operation.

At the autopsy the body was found in a frightful state of decomposition, and the microscopical examination of the various portions removed proved valueless. The gross pathology was in part the presence of a carcinomatous mass beginning in the lumbar vertebræ, which were softened and eroded, and surrounding the great vessels to the level of the second rib. The mass was as large as a man's arm, and is shown herewith. The left testis was found in the lower part of the abdomen and was cystic and about the size of a lemon. The prostate was present as a single small middle lobe. No vagina or uterus was found. The spleen was nodular, the liver normal. There was a metastasis, three by two inches in size at the attachment of the diaphragm to the right ribs. The left kidney and ureter were incorporated in the cancerous mass. The right kidney and the portal vessels seem to have escaped. The entire mass was firmly adherent to the spine. The direct cause of death seemed to be an occlusion of the abdominal aorta caused by the pressure of the growth.



Microphotograph of the solid portion of the original growth.

In May, 1903, about two months after the removal of the tumor, the patient was examined by Dr. Ferd. C. Valentine with reference to the genito-urinary conditions and the examination of the urine at that time would have indicated a diagnosis of oxaluria with mild catarrhal pyelonephritis.

103 West Seventy-sixth Street.

Tubercle Bacilli in Milk.—In order to determine the temperature which will kill off tubercle bacilli in milk, W. Rullmann (Münch. med. Woch., March 22, 1904) added highly virulent sputum to different samples and then subjected them to various degrees of heat. After sterilization, a certain amount was injected into guinea-pigs and an autopsy held several weeks later. All animals were found infected unless the milk was heated up to 68° C. for one hour with constant agitation. If rapidly cooled this milk will not suffer in taste, nor is the albumin, lecithin or enzyme in any way altered.

THE MODIFICATION OF MATTOLI IN THE OPERATION OF VON HACKER FOR GASTRO-ENTEROSTOMY.

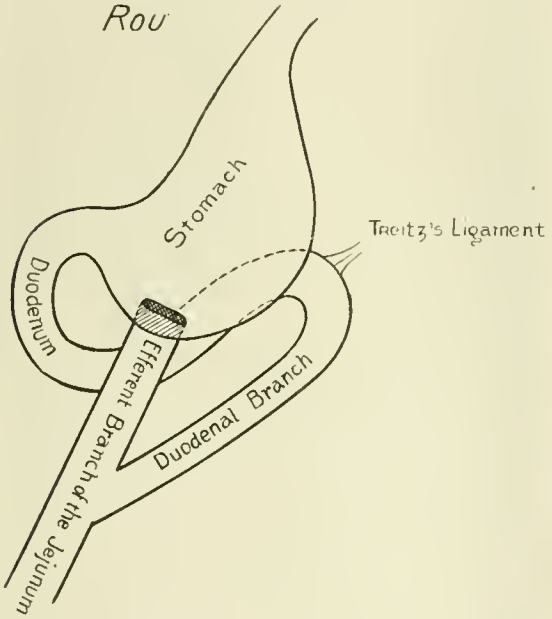
BY CARLO SAVINI, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN AT THE NEW YORK DISPENSARY.

MANY have been the efforts in gastro-enterostomy to obtain with less difficulty and danger the same results as those given by the operation of Roux. The modifications of Chaput and Doyen-Gallet belong to this class, but they are either incomplete or difficult to perform.

Mattoli of Rome has suggested a method which has appealed to my mind as being the most simple and complete and which is worthy of a more general notice than has thus far been accorded to it.

Roux's operation consists mainly in cutting through the jejunum and the mesentery about ten inches below the Treitz ligament, in attaching the

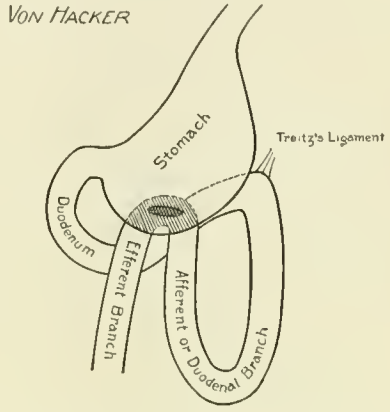
Fig. 1.



terminal or efferent portion of the intestine to the posterior wall of the stomach and in uniting the afferent or duodenal section to the intestine a little below the gastro-entero-anastomosis. A large opening between the stomach and the intestines and a free flow of bile and pancreatic fluid into the jejunum is in this manner secured. Post operation vomiting done away with and the possibility of *circulus vitiosus* avoided, it may be affirmed that this operation procures ideal results, regarded from the standpoint of a restoration of the physiological conditions governing perfect nutrition.

But Roux's method presents technical and other difficulties not to be overlooked. As the use of the Murphy button has many times proved to be unsatisfactory, two terminolateral anastomoses are lengthy and difficult if made with sutures. Once the first step in dividing the jejunum is accomplished the operation must be followed to the end, regardless of the patient's condition, and the surgeon is forced to make two anastomoses, in other words, to perform two operations. The danger of infection resulting from the opening of the intestines is also to be considered.

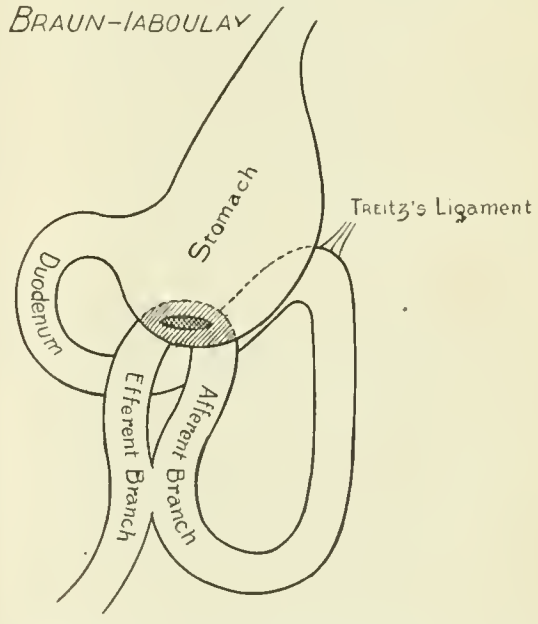
Fig. 2.



The foregoing are some of the reasons why an operation producing such perfect functional results is not more generally performed.

Von Hacker's (gastro-enterostomy posterior transmesocolic) is more simple and more speedy, and when well done is an operation procuring in most cases excellent results, though the possibility of the forming of a spur or valve closing the efferent portion of the intestine and the vomiting of bilious matter and food, often necessitates a secondary operation. In the Von Hacker operation the possible occurrence of a *circulus vitiosus* presents a very serious complication.

Fig. 3.



The Braun-Jaboulay modification, or the an-

astomosis between the two branches of the intestines corrects most of these disadvantages. But even when thus modified von Hacker's operation is inferior to Roux's.

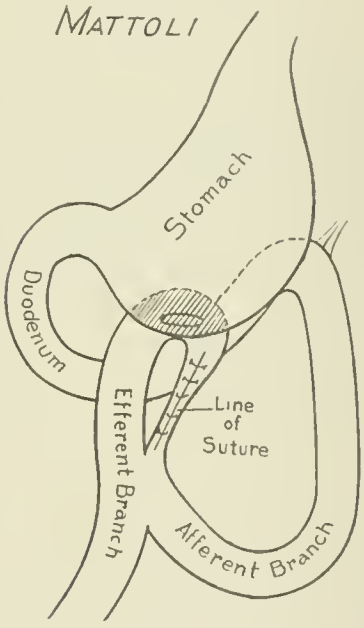
Mattoli's modification consists in transforming the modified von Hacker into an operation offering the practical advantages of a Roux, by closing with sutures the efferent or duodenal portions of the intestines between the two anastomoses. In other words, according to Mattoli, the operation should be performed in three steps:

First.—The jejunum is anastomosed to the posterior wall of the stomach as in the von Hacker.

Second.—The two branches of the jejunum are united and anastomosed together about three inches from the gastro-enterostomy as in the Braun-Jaboulay.

Third.—The afferent branch of the jejunum between the two anastomoses is held between the

Fig. 4.



thumb and the middle finger of the left hand placing the fingers longitudinally. The pressure of the index finger forms a groove in the intestine and the two resulting ridges are sewn together with a number of stitches of an interrupted or continuous suture; as a consequence this section of intestinal tube is here changed into a solid cord.

The *circulus vitiosus* is thus absolutely prevented. The bile and pancreatic juice cannot flow into the stomach and are entirely drained into the jejunum. The patient is not affected with vomiting after the operation and adequate nourishment can be administered as soon as the patient is out of ether. There can be no question that this operation is more safely and quickly performed than the operation of Roux. Besides by adopting this process the surgeon is not compelled to follow it to the end. He may desist at each step if the condition of the patient is not satisfactory.

Having had a recent opportunity to try this method with successful results, I will submit the history of the case.

Mrs. G. M., a widow, fifty years old, was perfectly healthy up to August, 1903, when she began to feel a pain in the right side of the abdomen. From October she had vomiting after meals. Denutrition increased and the vomiting became so frequent that by the middle of December the patient was unable to retain any food whatsoever.

I saw her first in December, 1903, and found her much emaciated, the tumor of the pylorus could be palpated and almost be seen through the thin walls of the abdomen. Having made the diagnosis of epithelioma of the pylorus I advised gastro-enterostomy as a preliminary operation to pylorectomy.

The patient was admitted to St. Mark's Hospital on January 2, 1904, and I performed the operation on January 5. An incision was made between the ensiform cartilage and the umbilicus, the peritoneal cavity was opened and the parietal peritoneum was fixed to the margins of the wound. The great omentum and the transverse colon were drawn outside the abdominal cavity, the latter being spread. The transverse mesocolon was opened with a blunt instrument, through the aperture of which the stomach was drawn and secured by the fingers of an assistant which brought the posterior walls of the viscus as far out as possible. The stomach being enlarged it was possible to perform the operation outside the abdomen.

Having located the Treitz ligament, I took hold of the jejunum and brought it near to the stomach in such manner that the portion to be anastomosed was 25 cm. distant from the ligament. The transverse colon and the epiploon were then replaced in the abdominal cavity. Sterilized towels and gauze sponges were disposed in such a way as to prevent infection of the peritoneal cavity from the contents of the intestines.

The jejunum was sewn to the stomach by three rows of sutures, the first seroserous, the second seromuscular and the third mucomucous. In the same manner I united the two intestines about three inches from the gastro-enterostomy. The afferent portion of the jejunum was then closed by a number of stitches according to Mattoli's method, as above described.

Ether anesthesia was employed and an intravenous saline infusion administered to the patient during the operation. The patient had a spell of vomiting as soon as she was out of ether, but has not vomited since. Four hours after the operation she was able to retain fluid nutrition and solid food was given on the second day. Convalescence was uneventful. The temperature has always been normal. The wound healed by primary union. Twelve days after the operation the stitches were removed and in two weeks the patient was permitted to leave her bed. She was discharged from the hospital on January 30, 1904.

206 East Seventeenth Street.

ASTHENOPIA: A CLINICAL STUDY.*

BY D. H. WIESNER, M.D.,
OF NEW YORK;
ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL.

UNDER the term asthenopia are included a long train of symptoms, subjective and objective, that result from faulty formation of the eyes, from an overuse or improper use of the organs of vision, or from both.

Definition.—The word asthenopia is a compound derivative, literally meaning without strong sight; ordinarily called "eye-strain."

Prevalence.—How common is the complaint "weak eyes"; "poor vision"! More and more frequent is this becoming; not so much so in rural districts, where life is less intense, but in crowded populous cities, where the rush of daily living demands constant application of the eyes at close range many hours in the day is asthenopia common. This fact is borne out when it is stated that more than 50 per cent. of the office work of the oculist is the relieving of asthenopia; the same percentage prevails also in those of our hospitals and dispensaries that have eye departments. Another side of this is evidenced in the very numerous advertisements in newspapers and elsewhere of the so-called "refracting opticians," "optical specialists," etc. Shop signs of these specialists abound; their positiveness is alluring: "If you have headaches come in." "Astigmatism properly corrected." How unskilful is the fitting of errors of refraction by these "specialists," oculists generally could testify.

Cause.—The cause of this prevalence is also clear. With the overcrowding in our large city comes the keen competition for position and even existence, often requiring the application of the eyes many hours of the day and far into the night, and that at close range; bad enough in the daytime, but worse at night by artificial illumination. The same applies to children and youth during the school years, for overstraining and overuse of the eyes by too long-continued application to study and school work will cause eye-strain.

Varieties of Asthenopia.—First, the accommodative. All eyes, in order to see clearly at close range, must call into action the ciliary muscle: this muscle surrounds the lens, inside of the globe, and by its action causes a further convexity of the lens, so that objects may be properly focused on the retina. Hyperopes of any large degree also have to use this muscle of accommodation for distant vision, because of the formation of the eye; it is readily seen, therefore, why with this refractive error symptoms of eye-strain are so common.

The Muscular.—The act of accommodation is accompanied and assisted by the act of convergence, both internal recti taking part in it: if this convergence be long continued it is easy to understand that an overstrained muscle will rebel and assert itself; furthermore, if for this reason, or for some other, the balance or equilibrium between the extra-ocular muscles be upset, the symptoms called muscular asthenopia will be likely to follow.

The nervous, hysterical or *psychical* asthenopia must be mentioned, for it is also met with; if accommodative and muscular asthenopia can be excluded, or if after careful examination and correcting of these conditions, the eye-strain symptoms persist, the nervous variety may be suspected and should be treated.

The purpose of this paper is to confine itself mainly to the accommodative and muscular variety of asthenopia, using the office case book to illustrate and describe the symptoms resulting from these conditions. While age may be a factor, and asthenopic symptoms be prevalent before the age of forty years, yet it is not uncommon to have patients over forty years present themselves with asthenopic symptoms, that is, in contradistinction from presbyopia.

Conditions of the Eye, Producing Eye-strain Symptoms.—In simple hyperopia they are common; in hyperopic astigmatism they are usual, and in compound hyperopic astigmatism they are the general rule. The severity of these symptoms, of course, depends on the amount of use and strain of the eyes.

In myopia, with the exception of the reduced distant vision—which is not to be called an asthenopic condition—eye-strain is not met with; with myotic astigmatism eye-strain symptoms are noticed, and also with the compound variety. The large majority of cases are those with hyperopia, with or without astigmatism, because it is in these cases that the accommodative act is so continuously required.

The Muscular.—This is a loss or upsetting of the equilibrium of the extrinsic muscles of the globe. These muscles bear, or are supposed to bear, a certain definite relation to each other, as to their action and power to roll the eye in one direction or another. If this power be disturbed it will manifest itself. Many of the symptoms to be mentioned are present in either or in both of these varieties.

The great relief resulting from the wearing of properly fitting lenses is a source of extreme gratification both to the patient and the oculist; that this may lead to overenthusiasm can be understood—to find that asthenopia is at the bottom of all the ills which flesh is heir to, is not a common experience with oculists. That it may be a factor in epilepsy is granted, and that partial relief from this condition often follows a proper correction of the eye conditions present is also granted; but that amelioration and cure of mental states or diseases follow lens or operative corrections of asthenopia is not a common experience. The scope of this paper is broad enough, but the time allowed for its reading makes it necessary to be brief.

Sex does not enter materially into the diagnosis; temperament does, however, and age is a factor, as most sufferers from eye-strain are

* Paper read at Annual Meeting of State Medical Society, January, 1904.

under forty years; and growing school children frequently complain.

Headache is a prominent symptom; pain in different parts of the head and in the eyes. This is of different kinds and varying intensity; at times sharp and shooting, at other times dull and throbbing; the temples and forehead over the eyes are favorite seats of pain; again, all over the frontal region and extending on either side to the temples; pain may be on top of the head and extend backward to the occipital region. If the ache be in or near the eyes it is generally due to the accommodative variety of this error—if further away, to the muscular; but it may not be always possible to distinguish the one from the other. These headaches are liable to come on in the afternoon and are carried through the evening and to bed, to be followed by relief in the morning. This ache is positive, intense; one case is recalled: the child came home from school with this pain and had to go to bed; this was followed by a vomiting spell; relief came in the morning. Several recurring attacks of this nature were relieved, and in time cured, by wearing proper lenses.

Blurring of Vision.—This is a common symptom both for near and distant vision; it happens that while looking at an object, suddenly all becomes blurred and blank before the eyes; or objects become indistinct, requiring a closing of the lids for a time, or the rubbing of the eyes to bring back clear vision: this condition is due to a sudden, though only temporary, failure of accommodation, that is, the ciliary relaxes, the lens becomes flat and vision is indistinct. Some call this "dizziness," some "swimming before the eyes." After a short rest the ciliary regains its tone and clear vision returns. When this is a prominent symptom the sufferer often becomes aware of it before its actual onset and can anticipate it by a short respite from work. This is often observed after some systemic disease, such as grip or typhoid fever; for in common with other muscles the ciliary participates in the general lack and loss of muscular tone and vigor. This condition must not be confounded with the paresis following diphtheria. Here there is a distinct nerve enervation, in asthenopia there is only a momentary loss of tone, inconvenient, to be sure, but only the symptom of a condition, not of a disease. Blurring of vision asserts itself after a continuous use of the eyes; thus in the morning it is uncommon, but is experienced toward the afternoon and early evening, particularly by artificial light. Under this head must be mentioned inability to see the blackboard work distinctly, so often complained of by students, old and young. Excluding a myopic state and poor illumination, this is due to a refractive error that the ciliary is not always or continually able to overcome.

Lacrimation.—Watering of the eyes is often a prominent symptom, and is probably reflex in its nature, due to an irritation of the tear-gland as a result of the eye-strain; excluding acute or chronic inflammatory conditions that cause lacrimation, there is an overproduction of tears: as they flood the conjunctival sac and are not carried off freely the moisture runs over the edge of the lids and down the face, causing decided annoyance; often redness and injection of the superficial conjunctival blood vessels accompany this lacrimation.

Diplopia.—Double vision is a not infrequent complaint. In some instances the feeling is that the eyes are crossed without the diplopia, in others there is a troublesome diplopia. Here the balance in the extrinsic muscles has been upset; the internal recti being overused and overstrained, are weakened to such an extent that the externi have strength enough to pull the eyes slightly beyond the point where objects fall on both maculæ simultaneously, and thus cause diplopia. This is not constant and does not produce an apparent squint unless of long duration. It is proper, however, to mention here that a decided squint is in a certain proportion of cases the direct result of an error of refraction.

Lid conditions should be mentioned.

Spasmodic twitchings of the lids come on without warning, and for a few seconds or longer the patient experiences muscular contraction of the levator or of the orbicularis, at times of both, alternately; a rapid, jerky spasmodic movement ending abruptly, to return again at uncertain intervals. A slight rubbing—massage—of the lids with the fingers will usually quiet this twitching.

Pinching of the eyelids is often met with, done either to increase vision or to accentuate it—astigmatics early and easily learn of the value and help of this act and practice it to increase and sharpen vision.

Blepharospasm.—It is readily seen how from a long-continued twitching of the lids or the pinching together, a condition of blepharospasm may result, while in most instances it is due to other causes—generally corneal—yet at times is encountered as a direct result of asthenopia, and is one of the hard things to overcome in the treatment of eye troubles.

Inflammatory conditions must be mentioned, as certain of them result from eye-strain, usually of the refractive kind. If bad hygiene, poor or malnutrition, rheumatism, gout and other diseases which are manifestations of the results of faulty metabolism, have been eliminated or recognized and cured, and the condition still persists, relief and cure of these symptoms promptly follow the correction of the asthenopia.

Blepharitis Marginalis.—An inflammatory condition of the lids in which the edges are red, somewhat thickened, and the seat of fine scaly particles or even crusts. If this persists there may be loss of some of the eyelashes—the picture presented being a peculiar one.

Hordeolum or Sty is an inflamed Meibomian gland; one attack is liable to be followed by another; painful, causing a swelling at the situation of the gland and often considerable swelling of

the lid, usually breaking down and relieved by the discharge of the pus.

Chalazion.—While not always an inflammatory condition, is also so frequently associated with an error of refraction that it may be mentioned as a result of asthenopia—the characteristic hard round swelling in the lids, rolling under the finger, not painful unless inflamed, which is rare, and gradually increasing in size. With proper correction and regular massage, relief may be expected.

As this paper must be brief and concise, some things have been left unsaid; while those said might have been elaborated; and if nothing startlingly new has been advanced there is also nothing uncertain put forward.

The purpose of the paper is to call renewed attention to a very prevalent condition, namely, asthenopia,—to its causes, manifestations and, most briefly, to its relief. Also, that many who are the sufferers from this asthenopia are induced by alluring and misleading statements to apply for relief to those who are unfitted and unqualified to treat them; how much these inefficient practitioners are on the increase is everywhere apparent. Relief from this state of affairs is needed. May the time soon be when the practice of medicine will be limited strictly to those who, by education and experience, are legally qualified to pursue it.

SOME CONSIDERATIONS IN THE TREATMENT OF TUBERCULOSIS OF THE TESTICLE.*

BY JOSEPH A. BLAKE, M.D.,
OF NEW YORK.

I HAVE been asked by your chairman to start a discussion upon tuberculosis of the testicle. As practitioners we are chiefly interested in the treatment of this condition, and consequently I have decided to limit myself to the expression of my views on the subject. In apology I may say that I have been unable to obtain the subsequent history of my cases as fully as I should wish in the short time I have had at my disposal.

My experience has been somewhat limited. I have at hand the histories of eight cases operated upon by castration with removal of the entire vas deferens in all, and in two with simultaneous removal of the seminal vesicle. In one case double castration was performed. I have never performed epididymectomy alone. In all cases the disease was restricted, as far as could be ascertained, to the genital apparatus, with the exception of one case previously reported to this section, in which, in three successive operations, I removed the kidney, ureter, left testicle, both seminal vesicles and most of the prostate. It is now nearly three years since the last operation on this patient and he is practically a sound man, having almost entirely recovered from the cystitis which accompanied his other lesions.

* Read before the Section on Genito-urinary Surgery, of Academy of Medicine.

The other patient from whom I removed the seminal vesicle with the vas and testicle was operated upon six weeks ago, and I have brought the specimen, since it shows extremely well the manner of extension from the testicle to the seminal vesicle often observed in these cases. You will observe that the disease has not extended continuously along the vas, but that, with the exception of two or three nodules at the distal and proximal portion of the vas, the remainder is free. This patient also had deep strictures necessitating a perineal drainage of the bladder, but he has been back at work for two weeks, his wounds being entirely healed before he left the hospital. None of the remaining cases have been followed, but none have returned for further treatment.

Returning to the consideration of operative treatment, since it is generally conceded that tuberculous foci in these organs should be extirpated unless in the presence of extensive tuberculosis elsewhere, we may classify the questions arising in the following order:

1. *Regarding the Nature of the Operation.*—(*a*) Whether castration or epididymectomy; (*b*) as to the amount of the vas deferens to be removed; (*c*) as to the removal of the seminal vesicle when involved.

2. *Regarding the Operative Technic.*—(*a*) In excision of vas deferens; (*b*) in excision of seminal vesicle.

Castration or Epididymectomy.—When both testicle and epididymis are involved, there is no question. Castration is the proper operation. When the epididymis alone is involved, many men of large experience advocate epididymectomy. It is extremely difficult to obtain trustworthy statistics upon the efficacy of this measure, particularly in regard to the question of local recurrence, yet one has only to glance over the reports of cases to find that not a few have a persistent sinus remaining or have to submit later to orchectomy. As I have already stated, I have never done this operation, possibly because I could not satisfy myself that the epididymis alone was affected. My preference is castration unless both sides are diseased, when I should leave one testicle if possible.

The gland is useless when the epididymis is removed unless for internal secretion and one testicle suffices for that. Horwitz states that he has not observed atrophy of the testes or diminution of sexual power after epididymectomy, but it is not clear that the cases observed were double operations. Nor is the length of time in which the cases were under observation after operation stated. In a man sixty-eight years of age, whom I castrated for enlarged prostate, when that operation was in vogue, sexual vigor with emissions was retained for nearly two years after the operation. If epididymectomy has no influence upon the sexual vigor, the fact is a strong argument in its favor.

The Amount of the Vas Deferens to be Removed.—In all my operations I have removed

the vas deferens with, usually, a portion of its ampulla. The importance of so doing is well illustrated by the specimen shown, and by a large number of reported cases in which the disease has skipped large portions of the vas.

The Removal of the Seminal Vesicle When Involved.—My opinion is that the infected seminal vesicle should be excised in every case in which the disease is limited to the genito-urinary tract, for the following reasons: first, that tuberculous foci in general should be removed as far as possible, and secondly, to prevent implication of the remaining testicle and the urinary tract. When we consider that in 50 per cent. and, according to some, 75 per cent. of the cases of tuberculosis of the testicle, the other testicle later becomes affected, we can appreciate the importance of eradicating the disease, particularly in the region of the seminal vesicles and prostate. Even after castration, according to V. Bruns, the other testicle becomes diseased in 23 per cent. of the cases. On the other hand the seminal vesicle is said to shrink away in a large number of cases when the vas deferens is removed (Horwitz).

Again, the operation for excision of the seminal vesicles is a difficult one and not to be lightly undertaken unless one is reasonably sure of his technic. In proper hands, however, when there are no other contra-indications its dangers are less than those of allowing the tuberculous focus to remain. In regard to the technic in operations upon the vas deferens and seminal vesicle, I have found the following method to be satisfactory:

In removing the vas with the testicle, the testicle is first excised with any skin that may be invaded, the incision is then carried up to a point opposite the internal ring and through the aponeurosis of the external oblique. The vas deferens having been separated the remainder of the cord is divided, and the vas being drawn upon the peritoneum is pushed away from it with the finger until it is freed down to the ampulla. A ligature is then tied about it as low down as possible, or it is evulsed, the finger of the other hand separating it at the ampulla. The wound is then closed, as in the repair of hernia. By this method a portion of the ampulla is generally removed with the vas. This method is usually preferred to that of Büngner, in which the vas is evulsed from the external ring. When I have removed the seminal vesicle, I have first excised the testicle and vas deferens in the manner described and have then attacked the vesicle through the curved perineal incision known as Zuckerkandl's. After freeing the dorsal surface of the prostate, the seminal vesicle is exposed by incising the layer of the rectovesical fascia binding it to the bladder. It can then be shelled out without much difficulty. At the same time any lesion in the prostate can be attacked and handled as its extent of importance may require.

SOME REMARKS ON TUBERCULOSIS OF THE URINARY BLADDER.

BY ALEX. B. JOHNSON, M.D.,
OF NEW YORK.

Tuberculosis of the urinary bladder usually occurs in combination with tuberculosis of other portions of the urogenital tract.

Among 35 cases observed by Casper in three the bladder was found to be the sole seat of the disease. In 14 cases the kidneys were also the seat of tuberculosis; in seven cases the genital organs; in two cases the joints; in five cases the lungs; in three cases general tuberculosis existed. In one case the patient was the subject of lupus.

According to Koch, the following modes of infection are possible:

(*a*) *In the presence of tubercle bacilli in the body*: (1) Infection through the blood current; (2) infection by way of the lymph channels; (3) infection by the excretion of tubercle bacilli through the kidneys with or without disease of these organs.

(*b*) *Through the introduction of bacilli from without*: (1) By cohabitation; (2) by catheterism.

Bladder tuberculosis presents itself to us clinically in most cases, as a more or less localized, occasionally diffuse process combined with tuberculosis of the kidney and ureter; as tuberculosis of the prostate and seminal vesicles, or of the epididymis and vas deferens. Such combinations are so general that many surgeons of large experience have never seen a case of tuberculosis of the bladder alone and not a few deny the probability of its occurrence.

As might be expected from the mode of infection, that portion of the bladder forming the trigonum and the parts adjacent to it are the most frequent seat of the disease. In advanced cases, however, a large part of the bladder wall may be involved. The lesions noted vary with the age of the process. In the early stage, localized swelling and congestion, such as we regularly see at the mouth of a ureter when the kidney is the seat of tuberculosis, are present. Later, tuberculous nodules of greater or less size occupy the affected area, and finally, tuberculous ulceration of characteristic form and appearance takes place and progresses with the formation of much cicatricial tissue. The organ becomes more rigid, loss of distensibility results and the capacity of the bladder may thus be greatly diminished. Mixed infection adds the lesions of other forms of cystitis.

The symptoms of bladder tuberculosis vary to the same extent with the seat of the lesion and are usually much complicated by the coexistent lesions in other portions of the genito-urinary tract. If, as rarely happens, the region of the trigonum remains free from disease the characteristic symptoms of bladder irritation may be slight or long absent. If the trigonum and vesical end of the prostatic urethra are involved the symptoms are marked. They consist of frequent

desire to empty the bladder and pain which is referred to the perineum, the course of the penile urethra, the glans penis and the sacral region. A severe spasm of pain usually follows the end of urination. The pain of tuberculous cystitis is severe and exhausting and many of these patients become addicted to the use of morphine. In advanced cases the misery of these unfortunates is pitiable in the extreme.

As a result of the local irritation, notably when the prostate is also involved, patients sometimes exhibit an abnormal activity of the sexual apparatus and may continue to copulate industriously, even when the disease is well advanced toward a fatal termination. Hemorrhage from the ulcerated areas may occur. The bleeding may be microscopic or so severe as to seriously diminish the patient's strength or even imperil his life. The intravesical bleeding may cause retention of urine of a painful and particularly distressing character. The condition of the urine will vary according to the presence of a complicating cystitis or a tuberculosis of one or both kidneys. The urine is usually acid, and if the kidney is also involved there will sometimes be polyuria and urine of a low specific gravity. The amount of pus in the urine will vary greatly and is scarcely to be relied upon as a typical diagnostic sign.

In nearly all cases tubercle bacilli can be demonstrated in the urine either at once or after repeated examinations. If the centrifuge be used it will very rarely be necessary to resort to the inoculation of animals to establish the diagnosis.

The general health of these patients suffers as is the case in tuberculosis of other organs. They lose flesh and strength and, if mixed infection is present, they will suffer from chronic septicemia accompanied by fever, night-sweats, loss of appetite and often from diarrhea. In such cases the pain is an important factor in producing deterioration of the general health.

Diagnosis.—Tuberculosis of the urogenital system is a disease of adolescence and young adult life. It may also occur as late as middle age but is rarely developed after the fifth decade. Men are more commonly affected than women.

When a young person comes to us complaining of painful and frequent urination, if he be a male we seek to exclude gonorrhea; if the individual is female, hysteria, a uterine displacement or diseased adnexa. If the urine is found to be purulent we further seek to exclude stone in the bladder or stone in the kidney. Search for tubercle bacilli will often demonstrate conclusively the presence of a tuberculous lesion somewhere in the genito-urinary tract. The testicles and vasa deferentia will often show the characteristic nodular enlargements of the epididymis and the thickened vas deferens. The finger introduced into the rectum readily tells us whether the prostate is hard and nodular and whether the seminal vesicles are increased in size and indurated. The tuberculous kidney is often slightly tender, although at an early stage of the disease it is rarely so much increased in size as to be readily palpated.

The cystoscope will then enable us to see the characteristic changes in the bladder, if such be present, but only too often we are able to see tuberculous disease beginning at the orifice of one or both ureters, indicating disease of the corresponding kidney. In fact, in by far the largest percentage of cases of bladder tuberculosis there will be such evidence of tuberculous disease in other portions of the genito-urinary tract, that we are obliged to regard the process going on in the bladder as of secondary interest from the point of view of surgical treatment. Not that the disease of the bladder is less serious or less important, but experience has taught us that until the other tuberculous foci have been removed we can do little for the bladder itself.

Treatment.—In many cases of beginning tuberculosis of the bladder the treatment consists in removing the complicating foci of disease in the kidney, the seminal vesicle, the prostate, the epididymis or the vas deferens as the case may be, and in letting the bladder alone. If the other foci of disease can be removed the bladder will often get well, provided the patient can be placed under favorable hygienic conditions, such as removal to a dry and equable climate, life out of doors, good food and the other measures which have been found useful in many forms of tuberculous disease.

If disease of other organs can be excluded it is my belief that general and hygienic treatment offers the patient a better hope of cure than any local operative measure. It is true that a few cases of tuberculous ulceration of the bladder have been greatly benefited and even cured by operative removal of the disease, but where one has been benefited ten, in my belief, have not, and a good proportion have been left with a permanent urinary fistula lined with tuberculous tissue. It has long been known that a bladder which is the seat of tuberculosis is often made worse by instrumentation, and the various forms of local treatment, so very useful in other kinds of cystites, usually fail to do good in cases of tuberculosis, and often do great harm.

There are those, however, who believe that improvement sometimes follows the periodical introduction of bichloride of mercury solutions into the bladder or the instillation of iodoform emulsion. The use of internal antiseptics in tuberculosis of the bladder is of doubtful value. Of the many used, creosote seems to bear the best reputation.

Certain operative measures may, nevertheless be called for in cases of bladder tuberculosis. In advanced cases the bladder sometimes becomes extensively diseased and greatly contracted. The sufferings of these patients are so intense as to be beyond endurance. Under such circumstances a permanent suprapubic opening made into the bladder for drainage may give great relief and is followed by marked improvement in the general health of the individual. In certain cases of severe hemorrhage from the ulcerated vesical

mucosa a suprapubic incision into the bladder, for the purpose of controlling the bleeding, may be called for. Under such circumstances the surgeon might properly proceed in one of several ways, according to the condition found. If an ulcerated area not involving the orifice of the ureter exists it might properly be excised and the wound closed by sutures. The curette and the actual cautery might be employed to destroy the base of the ulcer. If the orifice of the ureter is the seat of disease the kidney on that side is probably tuberculous and will perhaps require removal. The cautery might then be cautiously used for the control of bleeding preceded by the use of a curette. If the bladder is still in fairly good condition an effort should be made to close the wound, else a permanent tuberculous fistula will almost certainly result.

In women access to the bladder through the urethra is comparatively easy and in cases where the kidneys were not involved a number of surgeons have reported favorable results from curettage, cauterizations and applications to the diseased bladder made through a speculum. Such treatment may be tried preparatory to the hygienic measures before indicated, or even where such hygienic measures cannot be carried out.

My conclusions, however, in regard to the treatment of tuberculous cystitis are as follows: (1) If other tuberculous lesions of the genito-urinary tract exist their operative removal is sometimes followed by improvement and even cure of the process in the bladder, provided the patients are placed under the most favorable hygienic surroundings. (2) Operative treatment of the bladder alone in the presence of tuberculous lesions of other portions of the urinary tract is usually harmful rather than beneficial. (3) The local treatment of the tuberculous bladder by means of injections or applications through the urethra is generally useless and often very deleterious. (4) The internal administration of the drugs known as urinary antiseptics is generally useless. (5) Palliative operations, such as suprapubic drainage, may be useful in advanced cases. (6) The general or hygienic treatment, suitable climate, out-of-door life, etc., offers these patients the best hope of recovery. (7) Such hygienic measures should be preceded by the operative removal of tuberculous foci in the kidney, the epididymis, the prostate and the seminal vesicles if such exist and the patient is still in sufficiently good condition to bear the operative procedure. (8) In those rare cases where the bladder alone is affected over a moderate area only, the operative removal or destruction of the diseased tissue may be followed by improvement and even cure.

Typhus among Germans. Capt. Dannhauer, correspondent in German Southwest Africa of the *Lokal Anzeiger*, cables from Windhock that the number of soldiers suffering from typhus fever in the hospitals at Otjihaenena, Windhock, Okahandya and Karibib is 175.

A FEW CONSIDERATIONS CONCERNING THE MECHANISM OF DEVELOPING MENTAL DISORDER.

BY W. K. WALKER, M.D.,

OF DIXMONT, PA.;

FIRST ASSISTANT PHYSICIAN TO THE WESTERN PENNSYLVANIA HOSPITAL FOR THE INSANE.

HOWEVER convenient the distinction between "health" and "disease" as applied to opposed groups of phenomena, the physician who aims at early diagnosis and prophylaxis must recognize the fact that as distinct principles or entities neither has separate existence. More than a century ago Bichat, in expressing the relations of pathological anatomy to clinical medicine, used the following words: "It is not alone the science of these changes which primarily or secondarily develop gradually in the course of chronic disease; it includes the examination of every alteration to which our parts are subject, at whatsoever period of the disease." Three quarters of a century later Claude Bernard, in developing this conception along physiological and clinical lines, said, "Between any form of disease and health there are only differences of degree. No disease is anything more than an exaggeration or disproportion or disharmony of normal phenomena." From Bichat's time to the present—indeed, most markedly in the recent achievements in chemical physiology and chemical pathology do we trace the further development of this conception.

In no particular field, perhaps, is the relativity of disease and health more apparent than in psychiatry, although the almost universal acceptance of this view has not prevented the criticism by most laymen, many physicians, and courts of law quite generally, that in the determination of the existence of mental disorder we are prone to confound health with disease, and *vice versa*.

The study of the mental aspect of man can not be separated from that of his bodily functions; and mental disorder is to-day inconceivable except as a result of defective organization, perverted nutrition, or alteration in structure—with consequent disorder in functioning of the complex organ which immediately supports it, or of change in remote organs which minister to the brain's nutrition. We cannot always correlate observed nervous and mental phenomena with cell changes or their complex metabolic activities; nor is it reasonable to expect—from their peculiar nature—that we can ever attain the final explanation of morbid psychic phenomena in constitution of nerve cell. It is not too much to say, however, that we are beginning to understand how they may have their origin in nutritive changes which modify and interfere with the cellular mechanism upon which the highest cerebral function—the process of "associative memory"—depend.[1] We have increasingly accurate knowledge of this last named function and, with it, of the order and mode of development, that is, the "mechanism" of mental states whatever their character. Our present-day insight into the nature

of these inner processes, of their connection and interaction with the physical and chemical processes of the human organism is, in large part, psychology's contribution to the sum total of science, and its practical value to medicine cannot be over-estimated. A glimpse into this mental mechanism is essential to a clearer comprehension—not only of the early morbid manifestations of mind, but of the latest and most unmistakable symptoms of insanity as well. In this paper it is with the former aspect that I shall more particularly have to do; attempting to indicate the "gross anatomy," as it were, of evolving mental disorder from ideas and emotions which, with associated states of the organism, must be regarded as earlier phases and requisite preconditions to the clinical entities we commonly term insanity.

Insanity is advanced mental disorder marked by characteristic psychic symptoms. It is exhibited in conduct or action; this, with the frequently accompanying phenomena of illusion, hallucination, or delusion, is to be regarded, in the vast majority of instances, as merely the latest episode in the most recent chapter of the patient's history. "The lunatic's horrifying visions, panic fear, profound depression, and delusions of persecution are all constructed from the material of daily fact." From the earliest subjective symptom of disturbed or perverted sensation and perception, through morbid idea, impulse, emotion, obsession, and the more marked dissolutive phenomena of hallucination and delusion, to the final culmination in violent deed, there is a correlated series of psychic events having no sharp definition of the morbid from the normal. In their gradual transition, however, there are symptoms so distinctive of the mind's morbid functioning that they clearly foreshadow the more serious mental disorder into which they may at any time develop under favoring circumstances of exhaustion, toxemia, intoxication, or stress from any cause whatsoever.

Early slight deviations from health can be fully appreciated only through an understanding of the normal mental mechanism, and for this there is necessary a knowledge—not only of the general physical and physiological substratum upon which their development is conditioned, but of the "peculiar" manifestations of mind, the products of brain functioning. These, the most "personal" matters of the patient's life, are the images or materials of which the mind is composed; the individual sensory experiences and habit of associating and combining these into ideas, judgments, and beliefs; his intellectual preoccupations; his feelings, impulses, interests, personal passions, and special or characteristic mode of reacting to environing circumstances as determined not only by their nature, but by peculiarities of organization as shown by resulting ideas, emotions, and tendencies. Previous happenings in the individual's mental life are here of equal significance with those which pertain to his physical organism when considered in their relation to bodily diseases. And morbid mental states are only elucidated when thus viewed in relation to earlier psychic activities. The earliest indications may appear inconsequent to us because of our ignorance of the laws which govern their development, but this is no excuse for excluding them from our notice or allowing them to pass unheeded.

It cannot be urged that in thus considering idea, emotion, and impulsion, that we are dealing with something vague and intangible; all this they may be in the sense that they are not material, yet, as present to the patient's consciousness and *tending to material expression in attitude, word, or deed;* and as influencing life and its organic processes—as well as being the highest manifestation and result of it—we cannot consider them apart from the life of the organism as a whole. The modification of psychic events, when encountered as accompaniments of defective, perverted, or diseased states of the organism, are therefore as real as any facts with which the physician (as well as the psychologist) has to deal.

All mental development is dependent upon sensation; that is, upon transmission to the brain of the special sensations of sight, smell, hearing, taste, and touch, as well as of the innumerable muscular and organic sensations which stream into the sensorium informing the nerve centers of what is going no in the various outlying regions of the body. With normally developed sense organs and cerebral cells, with their connecting fibers, such impressions are associated in memory and fuse, combine, and organize into images and various combinations of images in accordance with laws which further govern their association, inhibition, and tendency to final transformation into action.

The expansion of sensations—the materials of the mind's growth—into images, and from these into the most complex combinations of images, is made possible by the marvelous complexity of the underlying brain mechanism. In receiving, combining, fusing, and associating these innumerable sensations there are impressed upon them certain characteristics depending upon peculiarities of the individual brain organization. Whether received, retained and associated, or recalled in normal or morbid manner, the sensation, image, or idea seeks to escape as movement; in this not only resembling, but following the law of all neural action; that is, first sensation, then movement. And just as the simple reflex varies in amount or intensity, depending upon the character and strength of the sensation or impulse and the varying conditions of sensory organ, conducting fibers, and receptive centers, so in the very complex psychic sphere we encounter variations, perversions, and disturbances depending upon the intensity or duration of the stimulus and condition of the receptive sensory, and of the higher inhibitory centers. While the final result in motor or secretory manifestation is primarily referable to the original stimulus (sensation), the defective, excessive, or disproportionate reaction must be

regarded as due to abnormal conditions in the underlying reaction organ—that is, the brain.

In the mind's upbuilding or associative process by "the delicate interlacing of the strands of experience in the composite pattern of the mental tissue" sensation is the essential and earliest element. In dissociative or disorganizing processes we look to the sphere of sensation (with its psychic equivalent—idea) for the earliest indications of mental disorder: for alteration or modification of previously known opinions; or impaired capacity for judging; these are usually revealed by careful search, whether the disorder originated in distant or outlying parts of the organism or in the complex sensory areas of the brain. The symptoms, in all their apparent disorder—from the earliest "sensory ingredient" and its more complex counterpart, idea, to final expression in movement, that is, in physiognomy, attitude, word, or deed,—present a definite order and uniformity, with variations depending upon differences of original constitution and "experiences" of the organism which manifests them.

It is a fundamental principle of psychology that every idea has a tendency to be transformed into action. Amid the multiplicity of our ideas but few result in action, however, because of the antagonizing or inhibitory influence of the many other ideas simultaneously present in consciousness which rob them of their impulsive power;[2] these latter, we say, result in inhibition of movement, hence the law as more generally stated that "every idea results either in movement or in inhibition of movement—in action or its reverse." Any one of the innumerable acts of our daily lives illustrates the operation of this law. Whether it be the complex muscular movements of our professional activities or the simplest manual tasks, fixation of the attention upon the matter in hand is necessary for their performance. There is thus a narrowing of the field of consciousness; the ideas involved encounter no opposing ideas and the appropriate movements follow of necessity and as inevitably as those of any reflex act. If the combination of movements in any particular act has become habitual, owing to the increased permeability of the nerve paths through such frequent repetition of the act, attention becomes superfluous and, according to the general laws of brain-habit, the most complicated muscular movements, once inaugurated, are performed without the necessary intervention of attention, or indeed, of consciousness. And so in the sphere of the emotions: at first consciously entertained, and perhaps with adequate exciting cause, they may, through frequency of repetition, long duration, or morbid intensity, attract all the forces of the organism; with the field of consciousness so narrowed that no conflicting ideas or emotions are interposed they become translated into action with clear consciousness; with blurred states of consciousness (the rule under stress of emotion and passion); or without any intervention of consciousness whatever, as so constantly noted in the outbursts of fury of the imbecile and epileptic.

Among the countless images of which the human mind is composed and which differ with the degree of culture and the experiences of the individual, there is unceasing change and variation. Indeed, clear consciousness for the individual exists only upon condition of such change and of continual renewal through varied sensations and emotions. So essential is this to healthy mental life that "capacity for change"—that is, ability to transfer the attention to a variety of objects—is one of the evidences of normal mind.

With all this multiplicity and variety of mental images and ideas we look for some order or system; and this we find in the trend of habitual lines of thought and in conduct as determined by emotions, inclinations, and appetites. "Human character" is but the result of organization or association of the sensations, images and ideas resulting from experience, in a manner which harmonizes with the emotions and desires of the individual. In all characters, however, conflict of these forces constantly occurs; but, depending upon the intensity of opposing ideas and emotions, a variable degree of "control" is manifested. "Stability is a term used to designate the degree or vigor of the controlling and coordinating functions which measure the individual's power to guide or quell emotions, appetites, and inclinations and make them subsidiary to healthy life. To do this is to modify such emotions by association with a complicated system of ideas. Ability to do this presupposes a capacity for seeing things in their normal relations—for giving events their proper importance and significance. Now the very essence of morbid states of mind consists of an inability to see things in their true relations and signifies a lessening of the ability to think or reason logically or with normal rapidity. There is disorder, perversion, or defect of the highest and most complex intellectual faculties; a break in the continuity of the mental processes; a narrowing or retrenchment of the field of consciousness with proportionately increased tendency for the dominating idea or emotion to be transformed into action. It is to the mechanism of this limitation or narrowing of the field of consciousness that we must look for explanation of the "change in character" and "weakening of the will," which terms have been used to indicate alteration in all that were regarded as highest and most complex in man's mental organization.

It is clear that what were regarded as manifestations of "will" are, in reality, *the results of will;* that is, of choice as manifested in words, behavior, and deeds. While these acts of choice never reveal the total secret of mind, they do represent the final outcome of its complex processes—conscious in part, but for the most part unconscious—and, as the resultant of all the higher faculties, they become indices of character, that is, of organization or association with some unifying principle of the sensations and images resulting from experience.

"At the threshold of all action lie reflex, instinctive and impulsive nervous tendencies."[3] Will,

or volition is but the highest form—the psychic equivalent—of physiological inhibition so universally an attribute of the highest and most complex centers. In the normal exercise of its function it distinguishes man from other animals in the degree to which he can control, regulate, or inhibit lower instincts, emotions, tendencies and habits. In morbid mental states the narrowing of the field of consciousness is equivalent to removal, or lessening of this higher inhibitory power as represented by opposing ideas and emotions.

As an illustration of narrowed field of consciousness due to impairment of associative memory from physical causes, I borrow one that is familiar to all—a physiological rather than a pathological one: Under the influence of fatigue or exhaustion we frequently have a sense of limitation of our energies and, at such times, experience a perceptible difficulty in thinking or reasoning; there may be a hesitancy in making decisions and in assuming responsibility. There is a failure of the judging or comparing faculty, and it is with difficulty that we see things in their true proportions. After food and adequate rest our exhausted organism recuperates and the normal equilibrium is reestablished.[4] In the bodily sphere this condition of exhaustion, if prolonged, is manifested in further depression of the vital forces—a condition which we habitually regard as furnishing the requisite soil for the development and operation of all exciting causes of disease—bacterial and otherwise. So in the psychic sphere it supplies conditions in which all sorts of undisciplined impulses develop and manifest themselves; the various modes and passions, such as anger, jealousy, suspicions, dreads and fears.

Careful investigation into the mental phenomena of "fatigue" reveals the fact that the predominance of any particular idea or class of ideas is based upon an emotional state which, vague and indescribable though it may be, is found to determine what ideas shall and what shall not occupy the attention. All attention normal, as well as morbid, is found to be based upon emotional states. We know that images and ideas as organized into opinions and beliefs are, with none of us, solely matters of carefully rationalized judgment, or products of purely logical processes, but at bottom they are largely matters of feeling as determined by peculiarities of organization, early training and surroundings and immediate or remote interest (Royce). So markedly is this the case that it may be stated as a dictum that it is to man's instinctive and emotional nature that we must look for both the mass and momentum of human conduct. Organic (bodily) sensations very clearly enter into this emotional background which plays so important —even dominant—a part in our make-up and in guiding and directing our mental activities. Ordinarily, that is in health, this influence is subconscious; it operates beneath the surface. In disease, however, it is not only brought more vividly into light and so is the more readily studied, but is often the chief characteristic, as well as one of the earliest symptoms of mental disorder. Because of its intimate relations with developing morbid ideas I shall briefly consider the double aspect of idea and emotion resulting from mutually influencing brain processes.

Exhaustion from any cause narrows the field of consciousness in the sphere of ideas by interfering with the activity of associative memory. Emotion narrows the field of consciousness by attracting ideas which harmonize with the particular emotion. Whether exhaustion is temporary from overwork, illness, or toxic states of the organism, invariably are there concomitant emotional states which present themselves as the milder fears or apprehensions. Normally leading to conservation of forces through precautionary measures in the avoidance of further fatigue, exposure, excesses, etc., they are so far salutary in their influence. With the continuation of the cause, however, and especially if it is prolonged and severe, these normal apprehensions (fears) may imperceptibly shade off into the "trouble-bearing expectations" such, for example, as distrust and suspicion of the motives of others, unreasonable dislikes, or ideas associated with bodily aches and pains, the fear of illness or accident, the loss of property, and so on to "the thousand and one needless worries over the future which are simply providence for the morrow gone mad."

As the healthy individual reacts promptly from all causes of bodily disease, so the mentally stable react from causes of mental exhaustion and depression. Through the activity of the higher controlling and coordinating functions the lower emotional forces are held in check and so are prevented from entirely dominating the individual. But, just as we encounter varying degrees of susceptibility to all external causes of bodily disease, so we meet with a wide range of susceptibility to causes of mental pain. In contradistinction to those characterized as "stable" we encounter the "sensitive" or "unstable" who are exceedingly susceptible to emotional disturbance and in whom crises of emotion leave permanent imprints. Rarely met with where the nervous organization is entirely normal, in those of such neurotic constitution slight causes quite commonly bring undue results either in intensity or duration of the emotion (or both), and we see disappointment, grief and losses resulting in emotional states, either temporary or prolonged, which vary from mere passive joylessness, dreariness, discouragement and dejection, to active anguish, fear of eternal damnation and finally, absolute and complete despair. Whether engendered by exhaustion, defective nutrition of brain cell, toxemic states, or by ideas which gain entrance and attract harmonizing ideas, the process, or mental mechanism, is essentially the same in all and develops and propagates itself according to laws as fixed and inexorable as any which govern purely physical phenomena. Under these conditions one idea or one emotion among many

may not only be increased in vividness and intensity, but may be longer entertained until it finally besets, possesses or obsesses the individual. This is because, in the defective or exhausted state of the organism, it becomes increasingly difficult to marshal before the "mind's eye" the various and complex combinations of ideas by which the original idea or emotion is regulated or controlled. Any idea, with its accompanying or underlying emotion, may thus usurp the attention with varying degrees of intensity from that degree normally requisite to a proper understanding of events as they come within our sphere of interest to "the all-absorbing, compelling, and dominating idea which, like Macbeth's ghost, will not down."

Such retrenchment or narrowing of the field of consciousness results in more than mere removal of other conflicting ideas; "the idea attended to becomes intrinsically clearer to the patient at the same time that the other contents of consciousness are blurred and obscured. By the mere fact of attention it is aggrandized in importance and given intensity and vividness." It is through the influence of attention that all higher development is made possible. Fixed ideas and obsessions are merely the morbid manifestations of this faculty; examples of what obtains everywhere in the mental sphere—of variations, not so much in kind as in amount and degree; they are examples of morbid physiology shading off into pathology. When we are confronted with this involuntary dwelling of one's thoughts in a particular direction; when one idea or one emotion among many becomes so intense that attention is drawn exclusively to it and all other ideas or emotions are repressed or inhibited; when we have such marked retraction of the field of consciousness as that evidenced by the occurrence of obsessions, we may know that we have a morbid type of mind to deal with—a mind that "cannot escape from the bondage of its own processes" and, as indicating its peculiar mode of action, is a criterion of its abnormality.

Arising in the most complex intellectual sphere morbid and fixed ideas and obsessions are apt to be the earliest signs of mental abnormality or tendency thereto; they take their coloring from the intellectual life of the individual but—more than this—they serve as indices to the lower emotional tendencies upon which their development is conditioned and which, later, come more prominently into view. These earliest symptoms, however, consisting of ideas and peculiar habits of thought "confided only to the consciousness which experiences them," like subjective symptoms of disease in other bodily organs, become diagnostic data only when divulged to one who is competent to interpret them—the physician. But it rarely happens that even the medical adviser is made acquainted with these most personal experiences until, perhaps, the underlying emotional element is more prominently shown; this heretofore subconscious factor now becoming apparent gives something tangible—something measurable to deal with in the bodily expression of feeling as evidenced in physiognomy, attitude, words, and deeds, or in modifications of circulation, respiration, and the various secretions of the organism made manifest in their totality by the accompanying impairment of nutrition. These become accurate criteria of inner and otherwise hidden mental states, and are of just as great significance in diagnosis as are the physical and chemical modifications of the secretory and other processes going on within glandular organs. As in these latter we may know their results or processes without in all cases being able to separate the products into their ultimate constituents, so with emotions; though we do not yet know all the physical and chemical conditions under which they appear, we can observe the process of their determining attention to a given kind or group of ideas; their vivifying influence upon these; and their tendency, once started, to develop and propagate until all the forces of the organism are diverted to them, proportionately narrowing the field of consciousness and by so much increasing the tendency to resultant action.

It is a law in psychology that the more intense or vivid an idea the greater is its tendency to result in action. We have seen how an idea is vivified by the mere fact of attention. Attention becomes most potent in narrowing the field of consciousness when it is determined or reinforced by emotion; in other words, we see that most vividly (clearly) which arouses emotion or feeling. Because of the very multiplicity of our ideas but few attain degrees of vividness impelling to action because ideas not in keeping with our wishes, desires and inclinations are inhibited or kept in the background of consciousness; such ideas can readily be controlled. Very different is it when our emotions are involved; under these conditions, we have to do with something which most intimately concerns us—our material or social welfare. Emotion and passion—far from being controlled by ideas—not only determine, but control them. It is in this way that grief over the loss of someone near and dear may be the pivot about which all our ideas revolve; indulged to the exclusion of all other emotions, with the concomitant depression of all the vital forces, it can very soon assume morbid proportions, readily labeled as such by the mere fact of its entirely dominating the mental life of the individual.

Fear, suspicion, jealousy and anger, are emotions which readily assume a morbid aspect; they constantly precede, as well as accompany, certain forms of mental disorder; indeed, they furnish the "materials" for their development. I can best illustrate their diagnostic value by the recital of a few exaggerated cases:

Case I.—L. K. W., aged forty-five years, was admitted to the Western Pennsylvania Hospital for the Insane, June 21, 1901. Maternal granduncle and an aunt were insane. The patient has had nervous dyspepsia for years. The earliest signs of mental disorder were observed in June,

1899, two years prior to admission. At first unable to sleep, he next grew timid, and tried to avoid meeting strangers. Becoming fearful that he would lose his position, he soon manifested other fears—apparently the outgrowth of the former; one of these was that his family would come to want. He threatened to kill himself and also his wife and children, but has made no attempt to do so.

Under examination the patient was at first reticent but soon talked quite freely; telling in great detail, how, after months of rapidly failing health from long continued "stomach trouble" he began to feel timid and "afraid." At first vaguely "fearful of everything," he one day, conceived the idea when called on to sign his name in receipt of his week's wages he might forget how to write it. Fully appreciating its unreasonableness, this fear, nevertheless, grew upon him until he decided to quit work in order to spare himself the humiliation which such failure would entail. Unwilling to reveal to any one his reasons for such cowardly behavior, he now worried about the real trouble of curtailed income with its potentialities of poverty and want. Unable to control or modify the original groundless fear, despite its far-reaching consequences, his general state of fear and anxiety became augmented, and other fears developed and multiplied. Vaguely suspicious of all with whom he came in contact, his fears took the more definite form of threatened danger to self, wife, and family. He felt that for some unknown reason, he was followed by officers of the law; that he was accused of committing some crime, hence his threat to kill himself and his family in order to escape ignominy as well as poverty. Ending his story with the statement—"Doctor, you're the only one to whom I've told the fool beginning of this trouble"—he expressed the hope that treatment might help him in the effort to throw off such feelings, and to get well. With improvement in his digestive functions, and, consequently, in general nutrition, encouraging suggestion and employment of such a nature as to keep him continuously occupied, he made a good recovery and continues well up to the present time.

Case II is illustrative of the development of fears, at first slight and transitory, into a settled state of suspicion, fear, and ultimately, into varied delusions of persecution, with transformation into appropriate self-preservative action in the way of attack. J. B., aged sixty years, admitted March 3, 1902. His mother suffered with rheumatism all her life and died of "paralysis." A brother died insane. The patient has had "sciatic rheumatism" off and on for years. He has always been "sensitive and nervous." Seventeen years ago he suffered transitory attacks of fear. At first these were merely in the way of ideas temporarily entertained. After a night marked by terrifying dreams as of being caught and crushed by falling timbers, a sense of fear possessed him. He would feel afraid to cross a bridge or ride in a street car. These apprehensions soon passed, however, and he appeared perfectly well. In September, 1890, he had an attack of "nervous prostration" lasting several weeks. In this he walked the floor constantly, worried incessantly (about his troubles, real and imaginary alike) and, later, grew suspicious of those around him. At one time he refused a certain medicine because "it might poison him." Though apparently recovering from this attack he became at times morose and sullen. Never fond of company he now avoided strangers, and while living, in the main, an apparently normal life, morbid fears frequently beset him, manifested later in attitude, words, and deeds. In 1898 he entertained the idea (though himself a Knight Templar), that "the Masons wanted to put him out of the way." He at this time grew suspicious of his wife and children, and one day accused a daughter of coming into his presence with a concealed knife with which she intended to kill him. In September, 1900, he attempted suicide by cutting his throat, giving as a reason for so doing that "death was to be preferred to his constant torture." In December, 1901, he made an unsuccessful attempt to kill his daughter, afterward stating that a voice had been telling him to do it, and that for a long time he had resisted, but was eventually "compelled to act." In the two or three months intervening between this occurrence and his commitment as an insane patient, he manifested, in addition to his systematized delusions of persecution, innumerable fears, and ideas of suspicion. Every move on the part of those about him had some hidden meaning; a given look influenced his heart, his stomach, or sexual organs; the table and china decorations conveyed to him certain meanings; he was worked upon by electricity, X-rays, etc. These delusions accompanied by an attempt to act upon them together with excessive and almost constant motor agitation led to his committment to Dixmont, where he soon subsided into a quiet and apparently normal state. To the casual observer, he is a harmless, inoffensive and, at times, even interesting and entertaining old gentleman. His delusions of persecution have faded away but examination readily reveals the existence of habitually entertained fears, and obsessions or besetments, all in the key of suspicion and fear.

This case presents, as its earliest psychic symptoms, morbid fears entertained at intervals for years without being divulged to any one. Finally becoming more obtrusive, as well as more continuously entertained, they attract harmonizing ideas, and later, all sensations, both of special sense and organic, are interpreted by the light of such morbid fears and suspicions, progressing to their inevitable outlet in action.

The following case is one which so clearly illustrates progressive mental involvement, with gradual abrogation of the higher inhibitory faculties by reason of the accompanying clouding of consciousness, that I give it in considerable de-

tail. Long continued indulgence in alcohol results in the impairment of the highest intellectual faculties and finally, complete domination by ideas and emotions which are characteristically the result of this toxic agent. In the mechanism of its development it is typical—not only of the class to which it belongs, but of many forms of mental disorder. Viewed in the light of its cause, the earliest manifestation in jealous suspicion is not less significant as a symptom of developing mental disorder than is the latest outcome in attempted deeds of violence.

Case III.—L. J. (colored), aged forty-seven years. Was admitted October 8, 1902. Insane eight weeks before admission, he was confined in jail for ten days because of threatening behavior with a shotgun. He believed that a mob was going to lynch him and said that he was only defending himself from an attack upon his life.

A steady drinker for twenty years, he had shown no mental abnormality except when drunk (and then but the usual evidences of intoxication), until two years ago when he became very jealous of his wife, accusing her, when under the influence of whisky, of unfaithfulness to him. This only when drunk. Two months previous to his commitment, however, he constantly accused her of all sorts of things; he also seemed fearful of every one, and later, declared that certain people of the community intended to lynch him. He armed himself with a shotgun and threatened to kill any one who might approach.

Under examination the patient, in great detail, tells of long-existing deceit on the part of his wife; next of flagrant acts on her part. He then relates the story of an assault by a negro on a little girl in the community which was attributed to him (all imaginary). Detectives now watched his house day and night. He heard voices at every turn telling him to prepare for death. Knowing himself innocent of any crime he determined to sell his life dearly and accordingly made preparations for defense.

Since his admission there has been progressive development of his mental disorder, he spends his entire time talking by "echo-phone" to detectives, county officials, his imaginary accusers, and recently to President Roosevelt, who, he says, has appointed him to some high official position in Washington.

From a mass of available symptoms illustrating the psychic development of this case I give these rather meager details which mark the onset and the progressive involvement of his faculties.

In the expressed ideas of suspicion regarding his wife we have the earliest symptoms of his mental disorder, with accompanying and underlying emotions of jealousy as later evidence of an increasingly narrowed field of consciousness. The corresponding morbid emotions direct his attention to this phase of his conjugal relations, and he reflects upon all actions and words of the suspected wife; these are distorted by his perverted imagination and made to fit in with his suspicions. He sees that which he expects to see and all evidence to the contrary does not exist for him because his consciousness is filled with that which his feelings tell him must be so. Narrowed down to this one idea, with his attention constantly assailed by attitudes, words, and deeds, which (though entirely imaginary) are proofs to him that his suspicions are correct, we see their logical outcome in ensuing acts. He first accuses his wife, then threatens her with violence, which is prevented largely by the accidental shifting of his now multiplying apprehensions and fears to other objects. That the jealous suspicions of his wife were inspired—not by actual deeds on her part, but were entirely the outcome of morbid conditions within the patient's own organism, we have further proof (if such were needed) in the shifting or transference of his suspicions and fears to his less intimate environment. The fear of impending danger, so common in alcoholic cases, he now attributes to accusation of crime, the sexual nature of which is the mark of its being but a continuation and further progression of his earliest morbid ideas. With the increasing clouding consciousness we also see further attempt on his part to explain his emotions of fear and apprehension of danger; this eventuates in delusions. "People are down on him" because of his race. He is accused of a crime (imaginary) common to his race. For twenty years holding the respect of the community in which he lived, he deplores the fact that his previous good record now counts as naught, and he constantly broods upon this thought. With "fear of disesteem" as its origin we observe a progressive narrowing of his field of consciousness to this and harmonizing ideas, all of which are made to fit in with his emotional state, no inconsistent ideas coming to consciousness to counteract them. He is now unable to give events their proper significance or see things in their proper proportions. Sensory impressions are soon misinterpreted. All sounds reaching his auditory centers being transformed (by his imagination) into voices made by a mob gathering to lynch him. Moving shadows are spies and detectives who hound his footsteps. By this time convinced that his fears have foundation in fact he takes necessary steps toward protection from the dangers which threaten his life, and arms himself with a shotgun.

The development of grandiose delusions since admission to the hospital is the logical outcome of his reflecting on the earlier entertained ideas, images, and emotions of fear later evidenced by illusions, hallucinations, and delusions. His morbid reasoning (whether conscious or unconscious) being, in effect, that since he is made the object of so much notice and attention on the part of the world at large he must be a personage of importance; and adequate reasons are evolved by his diseased imagination to explain such persecution. At first falsely accused of crime and hunted by the officers of the law, and later, by the mob, he, for some unknown reason

(so he argues) must be an object of their envy, and reasons for this are gradually evolved in his disordered imagination. He now states that it was all due to the known desire of the President to appoint him chief over all the detectives in the United States. Great wealth and possessions come as the logical sequence of great authority. We thus see this last stage attained by progressive gradations. He, to-day, offers millions upon millions to any one who will release him that he may go about his most important business.

In concluding these superficial and incomplete, though lengthy observations concerning the earliest psychic symptoms of disordered states I would not maintain that defects of judgment, exaggerated emotional states, or impulsive acts always are evidences of mental disorder. My aim has been to indicate how—as products of brain functioning—they may become such, just as the products of other organs through their excess, deficiency, or alteration in constitution, may gradually shade off into pathologic character; and this even in response to their habitual, and normal stimuli: the disproportion between cause and effect, in such cases, is explained by the general condition of the organism, or to a certain disposition and peculiarity of the body cells favoring such change. The cause, in other words, is found in the patient's own organism. In like manner undue intensity (quantity or amount), undue duration,—disproportionate reaction to all causes of mental activity may assume pathologic significance.

We cannot subject the product of brain functioning to chemical and physical tests such as are constantly our measures of accuracy in the diagnosis of diseases of other organs, but we can painstakingly observe these outward indications of hidden mental states, while extending our search for the cause or causes of such deficient, excessive, or perverted reaction—not only to the latest, or apparent, determining cause of idea and emotion (with their motor equivalents), but to the history of the patient's own organism for data pertaining to the evolutionary period of the disease; to previous habits of thinking, feeling and acting—in short, to the mode of reacting to cerebral stimuli, whether general sensory, emotional or ideal. In a disease where the evolutionary period comprises the entire previous life of the patient—as well as the lives of his progenitors—we, as a rule, have little difficulty in obtaining such earlier incidents of history which, as parts of the records of defect, or of exhaustion, stress and strain, reveal peculiarities of the individual brain as a reaction organ and, to this extent, they are facts of clinical importance.

Of well-marked diagnostic significance, it will be seen that they are of even greater importance in their prognostic relations; for, just as the ugly scars and unsightly depressions in scrofulous necks evidence previous tubercular adenitis and the existence of vulnerable tissue with its well-understood and definite relations to pulmonary tuberculosis, so the early morbid activities of mind as revealed in moods, emotions, impulsions and obsessions, are criteria of mental vulnerability or instability. Occurring under adequate cause or as a result of exhaustion, acute disease, or transient toxemia, even in the robust and stable (who promptly recover), they are of vastly greater significance in those less well-endowed by heredity. Such are more apt to succumb—not only to the influence of exceptional upheavals or calamities of acute disease, grief and disappointment, but at those "times of order-making" normally characterized by change in the body's nutritive processes; the times of greatest functional activity therefore of relative stress and strain: I refer to puberty and adolescence, pregnancy, the puerperium and lactation and the menopause. Whenever occurring and whatever the cause the psychical mechanism is much the same for all despite the wide diversity in their manifestations.

The intimate relation existing between impaired nutrition of the nerve cell through exhaustion, intoxication, the toxins of disease, and the various neuroses and psychoses has been well demonstrated and its importance cannot be overrated. But it must be remembered that the human organism is something more than a receptacle or laboratory for the production of various poisons; that there is a mutually acting and interacting influence between the brain and the vegetative and organic functions which minister to its nutrition, growth and activity: The science of medicine, with its correlative branches, deals with the influence of these latter. But psychology has come to the aid of medicine in further elucidating the *manner* of functioning of this most complex organ, showing how impressions received from the external world through the various avenues of special sensation and of all the outlying organs of the body as well, are the "materials" or "ingredients" by which it expands; and also that, while thus developing it not only acquires its own particular manner of responding to stimulation from without, but further reacts upon the organic functions. "Our whole body in every instance resounds in every part to the variations of our brain activity, and the normal functioning of our organism depends in a large degree on the right work of these central stimulations" (Münsterberg).

The majority of all cases of fully developed insanity represent brains defective by heredity and made more so by repeated injury from toxins of chemical or bacterial origin, with inherent defect in associating and combining the ingredients (images) of the mind's growth. Having marked morbidity in their individual system of thought or ideation, the result of long-indulged emotions, it may be, which, however initiated, are later dependent for their continuance upon certain conditions of the organism; they gradually become related to all the mental forces of the individual; with habit stepping in to fix and, ultimately, to organize into a consistent whole such morbid ideas and beliefs, the very origin of which may

be forgotten. As the disorder progresses the higher faculties are bedimmed and clouded; special sense impressions fail of correct interpretation, or rather, are interpreted in the light of the prevailing emotions, and phantoms, or fictitious objects, dependent wholly upon the fancies, fears, and suspicions of the disordered brain which conceives them, are projected into the outer world where, as illusions and hallucinations, they become to the sufferer further proofs of existing cause for said morbid emotions. Thus vivified and accentuated, and with higher inhibitory factors abrogated, they become translated into appropriate deeds upon the slightest, and often quite accidental, determining circumstances. That which at first existed merely as a proneness to a certain mental attitude we constantly see thus transformed into an irresistible tendency evidenced in disordered conduct. This is the essence of insanity.

Our relative helplessness in the presence of fully developed mental disorder is explicable in the light of our knowledge concerning its psychical mechanism. Appreciation of our limitations in psychiatrical practice prevents us from making useless attempt to regenerate the idiot and imbecile; that is, to repair destruction or damage of neural tissue sustained before birth, or before the evolution of the mental faculties in childhood. But at the same time it leads to more painstaking efforts on our part to develop by special education the remaining spark of mental life in those who are thus congenitally defective. It also results in a keener appreciation of the varying degrees of vulnerability, and of the truth in the observation that "the greater the inherited or congenital defect or weakness the more easily does the organism react to the evil influence of a bad environment, and the more hopeless will be the efforts to raise it to the normal."

All available evidence of morbid brain functioning, whether manifested in idea, emotion, or act, becomes of clinical importance, and by so much enables us the better to exercise that highest function of our art—of guiding the vulnerable individual through periods known to be fraught with danger to such an imperfect organism. Revealing "the weak link in life's structural chain" these earliest indications are of the greatest importance from the standpoint of prophylaxis. In the early stage—while the disturbance is "functional"—we may hope to accomplish much through removal of the exciting or determining cause, whether this is exerted through other links, as of overworked or defective organs of special sense—the "tools of the mind"—excessive expenditure of physical or mental energy, emotional stress, or poisons and the toxins of disease known to expend their injurious influence upon the delicate structure of nerve cell. And it is not too much to say that in this stage we can, in many instances, prevent the development into graver mental disturbances, from which they differ, not so much in quality as in degree.

Prevention, which is always paramount to cure, is thus seen to be most important where the psychoses are concerned. Indeed, in a large proportion of cases the one hope lies in prophylaxis, and this is only accomplished by early diagnosis, which depends upon recognition of the abnormal nature of idea, emotion, and impulse, together with a study of the condition of lowered resistance under which they develop. Whatever their origin it is through their interpretation by the light of the laws which govern the mental movements that these earlier slight indications become instinct with meaning to the physician, as well as momentous for the future welfare of the patient.

THE AMMONIUM SULPHATE METHOD OF STERILIZING CATGUT.

BY WELLER VAN HOOK, M.D.,
OF CHICAGO.

The claims of the Claudius method of catgut sterilization by prolonged immersion in iodine solution, which I tried on account of its simplicity, have not been substantiated in my experience. The catgut has not an agreeable handling quality and often becomes fragile after prolonged storage. Moreover, while we may not doubt the statement of conscientious, trained and able observers that the iodine catgut is sterile, we have a comforting sense of perfect security in using a suture material that has been subjected to the action of boiling water. For these reasons I have returned to the ammonium sulphate process of Elsberg with such satisfaction that I feel it my duty to commend it.

The simplicity and convenience of this method are such that any nurse can carry it out. For more than two years I have employed it with the utmost satisfaction, entrusting the details to the operating-room nurse. A number of my colleagues have successfully used the material prepared under my direction. The method depends upon the principle, as stated by Elsberg (*Centralblatt für Chir.*, 1900, p. 537), that organic substances are insoluble in the fluids by which they are precipitated from their solutions. A saturated solution of ammonium sulphate answers these requirements, and Elsberg has shown that the boiling of catgut and other organic materials in such solutions for a period sufficiently long to insure sterilization does not seriously affect their surgically desirable qualities.

The weakening of catgut by sterilization is of serious import. I have found that slightly chromicizing the material before sterilization prevents it from weakening and softening, and yields a product more easily handled and tied. After exhaustive tests extending over more than two years, the product being used by myself in hundreds of operations at Wesley Hospital, the fol-

lowing routine of selection and preparation is warmly recommended:

At the outset a catgut of unimpeachable quality must be chosen and the surgeon will do well to arrange for a continuous supply of uniformly reliable material. It should not have been weakened by bleaching or polishing. Select raw, rough, unbleached material. Soak for a week in pure ether or a mixture of chloroform one part and ether two parts. Wind on glass spools in single layers. Soak for three days in aqueous solution of chromic acid, 1 to 1,000. Boil for twenty minutes in water to which, while boiling, chemically pure ammonium sulphate has been added until the crystals cease to dissolve. Wash the catgut for half an hour in cold sterile water. Store as desired. I place the spools in a solution of corrosive sublimate, one part in ninety-five per cent. alcohol, one thousand parts. Should the material become infected, it may be reboiled.

A SEVERE CASE OF MAJOR HYSTERIA (TRAUMATIC NEUROSIS) FOLLOWING AN ACCIDENT; RECURRENCE OF SYMPTOMS AFTER A SECOND ACCIDENT; ABSENCE OF DAMAGE CLAIMS IN BOTH INSTANCES.*

BY THEODORE DILLER, M.D.,
OF PITTSBURG, PA.

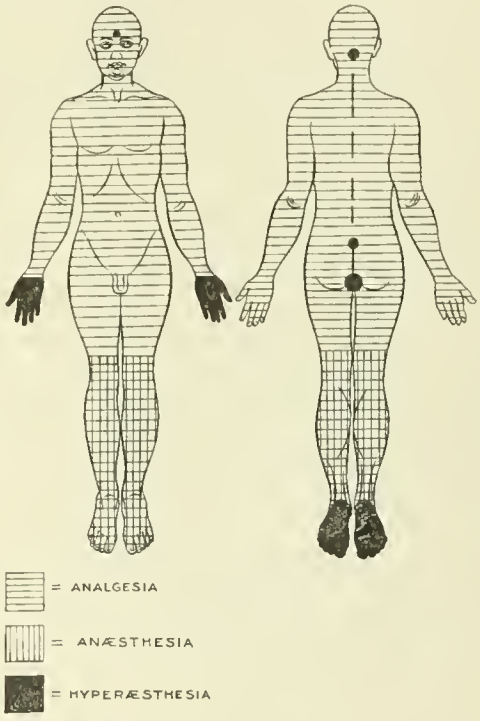
The following case of major hysteria is, I believe, worthy of note for two reasons: First, because of an unusually interesting array of clinical symptoms, among them high fever, subnormal temperature, greatly accelerated respiration rate with practically normal pulse. Second, because the symptoms originally followed and are doubtless to be attributed to an accident, and recurred after a second accident; and because there were no grounds for damage suits, which were not entered.

It is often quite glibly said of a patient suffering from hysteria or neurasthenia (or both) which follows and results from an accident and where damage suits are brought, that the symptoms would not have occurred if there had been no ground for suit, or else that they would have soon subsided and that they will quickly, if not instantly, disappear after damages have been awarded and paid. This attitude, which is common to defending attorneys and to many physicians, does, I believe, a great injustice to many who suffer from hysteria and neurasthenia following an accident.

I think that there can be no doubt whatever that the symptoms of such patients are commonly exaggerated, both consciously and unconsciously, by a pending damage suit; and that improvement is greatly hindered by a pending suit. I further believe that the rate of progress toward recovery is often greatly accelerated by the settlement of a damage claim; although an instance of a complete and instantaneous recovery of which so much is heard, has never come under my observation. The psychology of all this is easily explainable, but need not detain us here.

To illuminate this subject, two sets of observations are badly needed. (1) Of cases of hysteria and neurasthenia resulting from traumatism where no damage claims are made or financial benefits expected to accrue therefrom. (2) Detailed accounts of the post-settlement course of such cases.

The case to be reported is a significant example of the first-named variety of observation. In a later communication I hope to contribute something to the second.



My case is as follows: A single man, a bridge inspector, aged twenty-two years, was admitted to the Allegheny General Hospital on July 14, 1903. Thirty months ago, while serving as a sailor, he sustained a severe fall on a United States vessel, striking on his back across a tense rope. He was rendered unconscious, and remained so for three days. He lay in bed for three months suffering various pains, and with great loss of muscular power in both legs. During this time he suffered from frequent "attacks," each lasting two or three days, when both legs "stiffened out" and the patient became quite helpless. The intervals between the "attacks" were only six or eight hours. Then his legs felt "numb." His left leg was more affected than the right, and was often "stiff and trembling-like." He always felt the "attacks" coming on by beginning stiffness in his legs.

At the end of three months he was removed from bed to a chair. His legs were now no

* Paper read before the Allegheny County Medical Society, Jan. 19, 1904.

longer stiff. Two or three weeks later he was barely able to stand alone. Then he began to walk a little; and nine months after the accident he was able to go around at a "pretty lively gait." He still suffered some pain—in the soles of his feet and in the popliteal spaces and in the left side of his back (probably hyperesthesia). In general, he felt quite well, began work for a railroad as a bridge inspector and continued steadily at this occupation until two months ago.

At this time he met with a second accident, a fall of twenty feet from a bridge. Following this accident he suffered pains in the head, neck and abdomen, small of the back, and in both legs, more in the left than the right. Severe frontal and occipital headaches which were at first marked symptoms, have now considerably abated. Once or twice a day for a period of about thirty minutes his "legs stiffen out."

For a period of six weeks following both these accidents the patient was catheterized. Following the first accident he alleges a bed sore had developed. (?)

Examination, July 16, 1903.—Mental State: Patient is very anxious and apprehensive. He tells his story in a vague, halting and disconnected manner, although he was quite voluble.

Motor System.—The left foot is strongly contracted in a position of talipes equinus. The arch is much increased. Attempts to extend the foot are quite painful and are vigorously resisted. There seems to be much loss of power in the legs, more marked in the left than in the right. There is no apparent atrophy. Much fibrillary twitching develops in the left calf with attempts to extend the foot.

Sensory Functions.—There is universal analgesia, except over the following areas which are intensely hyperesthetic, viz., soles of feet and palms of hands, a spot about the size of a dime just above the root of the nose, a somewhat larger area over the occiput, several areas along the spine with a larger and especially well-marked area over the lower sacrum and coccyx. The lower limbs from a little above the knees downward except over the dorsum of the left foot and over the soles exhibit loss of contact as well as loss of pain sense. (See charts.) Visual fields are both markedly contracted.

Tendon Reflexes.—Both knee-jerks are quick, the left being longer than the right. Babinski toe reflex is absent.

The spine seemed normal; and in other respects the examination was negative. Subsequent examinations showed a good deal of shifting of the areas of anesthesia and hyperesthesia, with a gradual diminution of their extent and intensity. On August 1 pain sense and contact sense seemed nearly normal, the points of hyperesthesia at the root of the nose and over occiput had disappeared and the visual fields were quite normal. Hyperesthesia along spine and in soles of feet and palms was much less in degree. The contracture of the left foot was considerably less marked. In short, the patient had greatly improved in every respect under treatment, the chief features of which were suggestion, isolation, and hydrotherapy. On August 14 the patient, without warning, left the hospital.

Remarks.—It only remains to speak of the temperature, respiration, and pulse. The generally bizarre character of the temperature curve with the wide and sudden variations and the absence of changes in pulse and respiratory rate which would ordinarily correspond to the temperature curve in febrile conditions is the most noteworthy feature. The respiration rate was generally much increased in frequency, ranging most of the time from to 30 to 60. It bore no relationship to the pulse rate. For example on July 26 when the respirations were 60 a minute, the pulse was 66 while the temperature was 107° F. The pulse rate was remarkably steady considering the wide variations in respirations and in the temperature. Most of the time it was between 65 and 75. Rarely did it go below 60 or above 80. The temperature on the other hand ranged from 96° to 109° F.; and the respiration rate from 18 to 60, being much of the time above 40. The respiratory rate gradually subsided as the patient improved.

Without going into tedious detail, it may be stated that careful examination of the thoracic and abdominal viscera were made both by Dr. Ohail and myself to discover if possible any organic disease; for it is of course well known that hysteria may be associated with and indeed spring from organic disease. Our examinations discovered no organic disease.

The case, I believe, can therefore be regarded as a clear one of major hysteria. The permanent stigmata consisting in the contracture of the left foot and the sensory changes named including the greatly restricted visual fields constitute positive evidence of hysteria, from which one can make the diagnosis of this affection with great confidence, and which also gives one a much greater feeling of assurance than is possible in those cases where the evidence is largely or wholly negative in character.

That these marked variations in temperature are possible as symptoms of hysteria is ample evidence that although we regard hysteria as a mental disease it is one which may influence the so-called vegetable functions of the body. The altered pulse and respiration rates illustrate to a degree the same fact.

Note.—January 12, 1904 (five months after he eloped from the hospital), I learn that the patient has not only maintained but continued the improvement made in the hospital.

Sanitary Training School in Manila.—The Board of Health for the Philippine Islands reports the establishment in Manila of a course of instruction for provincial health officers. This course extends over a period of four weeks, is wholly practical, and is intended to remedy deficiencies in sanitary training and induce common methods of executing sanitary work by the various provincial boards of health.

MEDICAL PROGRESS.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

A Macroscopic Test for Leucocytosis.—It is not seldom observed, according to C. Hirsch and E. Stadler (Hoppe-Seyler's Zeitsch., Feb. 20, 1904), that urine containing pus, as soon as it becomes ammoniacal, acquires a slimy or ropy consistency. This fact was applied by Donné in his well-known test for pus in the urine, namely, the addition of concentrated caustic potash solution to the urine and shaking the latter, with the production of a marked viscosity. This test has been modified by J. Müller for the detection of leucocytes in the urine, in the following manner. To 5-10 c.c. of the suspected urine is added, drop by drop, officinal KOH, the mixture being vigorously shaken after each addition. The leucocytes swell up and impart the slimy characteristic to the mixture. If the latter is now shaken and the test-tube is then held quiet, it is noticed that the air bubbles in the ropy solution either rise very slowly or, if the mixture be very viscous, do not rise at all. This reaction is positive in the presence of 1200 leucocytes per cubic millimeter. An excess of KOH is to be avoided, for this dissolves the leucocytes. The author was stimulated to try this test for the detection of leucocytosis in blood, with good results. The blood of a leucemic patient, containing 400,000 leucocytes per cubic millimeter was examined. Twenty c.mm. blood were mixed with 5 c.mm. .9 per cent. salt solution. To this KOH was added drop by drop and the mixture became jelly-like. On shaking, large air-bubbles appeared and these rose very slowly. This phenomenon was obtained in cases of inflammatory leucocytosis, varying from 20,000 to 40,000. In these the results were less exaggerated and of shorter duration. Militating against the practical value of this test is the fact that normal blood with 8,000 to 10,000 leucocytes, acquires under the same treatment a viscous character. In the cases of marked leucemia the enormous gelatinization would serve to indicate a high leucocytosis. The theoretical explanation of this reaction is as follows: According to Kossel in the solution of the nuclei of the leucocytes by the KOH, the nucleoproteid is decomposed into alkali-albumin and the sodium salt of nucleic acid. The latter swells to a jelly. The further addition of KOH, or boiling, causes the formation of nucleic acid B, which no longer gelatinizes.

Is Diphtheria Transmissible by Water?—Having been called on several occasions to determine whether drinking-water was the source of sudden outbreaks of diphtheria, F. Seiler and W. de Stoutz (Rev. Méd. de la Suisse Romande, March 20, 1904) made experiments to find how long the Klebs-Loeffler bacillus would live in water. Having isolated a virulent culture from the throat, they infected 10 c.c. of normal bouillon, and the next day added one drop of this to one liter of distilled water in a sterilized rubber bag, and two drops to three liters in another bag. After thorough shaking, the bags were left at 18° C. for twenty-four hours. Then one drop from each bag was implanted on serum and left in the incubator eighteen to twenty-four hours. Typical colonies resulted and the individual bacteria had the morphology of the Klebs-Loeffler. Every day for nine days a fresh drop was taken from each bag and a culture made of it with positive results. In another series of experiments the water was implanted with a tiny piece of serum culture, and not only did the bacilli remain alive and virulent, but even increased in number from day to day in the distilled water left at ordinary temperature. Larger quantities of water, 10 to 15 liters, were then taken, and in every case the addition of a single drop of bouillon culture was sufficient to give positive cultures for from nine to twelve days, the time during which the tests were continued.

The Bactericidal Reaction in the Blood Serum of Typhoid Cases.—Tests which show that the bactericidal action of the blood serum of typhoid patients afford a more delicate diagnostic measure than agglutination are advocated by R. Stern and W. Korte (Berl. klin. Woch., Feb. 29, 1904). The principles involved in the method are as follows: A quantity of the suspected serum is rendered inactive to 56° C. To this is added a mixture of normal serum, containing the complements, and typhoid bacilli. By constant dilution of the serum to be examined, it is possible to determine the smallest amount which displays any bactericidal action. The serum taken from the patient is heated in a hot water bath to 55° C. in order to render its complement inactive, and then diluted with normal salt solution, 50, 100, or even a greater number of times. A series of test tubes are then filled with ½, ¼, ⅛, etc., of the original dilution together with sufficient saline solution to make 1 c.c. To each tube is then added 0.5 c.cm. of a 1-5,000 twenty-four hour culture in bouillon of typhoid bacilli, and also 0.5 c.cm. of fresh rabbit serum diluted with normal salt solution. Controls are also made on plates. Each of the test tubes then contains 2 c.c. of fluid and the bacilli and also the suspected serum in varying amounts. The tubes are now placed in the incubator and then the contents are planted out on agar plates, after three to four hours. The plates are then placed in the incubator for twelve hours, after which they may be inspected. Or the tubes may be kept in the incubator for eight hours, and conclusions drawn from the presence or absence of any turbidity. The latter method, although more rapid and simpler, is often invalidated by the presence of impurities in the serum. In this manner 32 cases of typhoid were observed and as a control, the serum from 23 patients who had never had typhoid. The reaction was manifested readily with a solution of 1-1,000; in the majority of cases even with 1-50.000 and the highest dilution observed was 1-4,000,000. The tests are especially applicable to those cases where the agglutination test is absent, appears late or can only be elicited with a relatively high concentrated serum, so that some doubt exists whether it is really produced by a typhoid infection.

The Aceton-content of the Organs in Cases Dead from Diabetic Coma.—The relation of aceton to diabetic coma has never been clearly defined. H. C. Geelmuyden (Hoppe-Seyler's Zeitsch., Feb. 20, 1904) finds that the organs of diabetics contain much more aceton than the corresponding organs of normal individuals. In both cases the liver has the smallest content in aceton. In diabetics the urine may contain more aceton than the blood. In attempting to explain the origin of pathological secretory products belonging to an intermediate metabolism, the author considers three possibilities: Either the substances in question are not produced in the normal organism, in which case they are the result of a perverse metabolism or else they are formed in the normal organism. In the latter case they are either formed in small amount, and appear in the excreta in larger amounts only as the result of an exaggerated physiological process; or they may be normally produced in large amount, only to be transformed into other substances. If by virtue of a diminished oxidation this transformation does not take place, then the original substances appear in the excreta. It is found that oxybutyric acid and diacetic acid are in-

termediate metabolic products, which are normally formed in the body in large amount, to be transformed into other substances under the influence of normal nutrition and metabolism. The author believes that carbohydrates and aceton-bodies are united together in the intermediate metabolism by means of a synthesis, which is necessary for the further transformation of the aceton-bodies. The absence or incompleteness of this synthesis leads to an accumulation of aceton with its consequent elimination from the organism. The possibility of this synthesis is supported by the fact that normally glycuronic acid, a carbohydrate derivative, unites with aceton.

Development of Hemolymph Nodes in Adipose Tissue.—Extensive experimental investigations conducted by A. S. Warthin (Proc. of Path. Soc. of Phila., Dec., 1903) prove that the histogenetic relations existing between lymphoid and adipose tissue are so close that a transformation of either one into the other may occur. A cyclia alternation between lymphoid and adipose tissue occurs throughout life. In old age the development of lymphoid tissue is lessened or comes to a standstill and the existing lymphoid structures undergo fatty atrophy and fatty metaplasia. In embryonic development of the formation of lymphoid tissue may be coincident with or follow the development of the primitive fat tissue. Not all lymph-nodes, however, pass through the stage of the primitive fat organ; the majority probably develop directly from the mesenchymal organs. A transformation of fat lobules into hemolymph nodes occurs in the human fetus. Under pathological conditions the development of hemolymph and ordinary lymph-nodes in adipose tissue may be greatly increased and such structures may be formed in regions where normally they are not found. The relationship between hemolymph and adipose tissue is more intimate than between the latter and ordinary lymph tissue. An analogy of the process is seen in the lymphoid transformation of the fatty marrow occurring in anemia and leukemia. In some of the lower vertebrates the close relationship between the hemolymph nodes and adipose tissue is seen in the persistence of adipose tissue of a fetal type (the so-called hibernating gland). Evidences of hemolysis and elaboration of blood-pigment are found in the fat cells as well as in the endothelium of this tissue, so that it may be regarded as a more primitive form of hemal organ than the hemolymph node, differing from the latter in the absence of lymphoid cells and the non-development of blood-sinuses. The steps of the development of the nodes in fat are as follows: (1) A dilatation of the capillaries of small fat lobules, the first stage resembling an angiectatic fat lobule. (2) A removal of the fat from the cells, immediately along the dilated capillaries and their conversion into reticular cells. (3) An infiltration or development of lymphoid cells in the meshes of the reticulum along the dilated capillaries, and an extension of the lymphoid cells between the neighboring fat cells. (4) Through the atrophy of the intervening fat cells and the confluence of portions of the dilated capillaries, blood sinuses are eventually formed. The reticulum traversing these may be derived from the original fat cells or arise through a proliferation of the endothelium and reticulum bordering upon the capillary. (5) Lastly, the fat is removed from the reticulum, the latter is uniformly infiltrated with lymphoid cells, the blood sinuses are still further developed and the characteristic structure of a hemolymph node is obtained.

The Capsule of Anthrax Bacilli.—An excellent stain for bringing out the capsule which surrounds anthrax bacilli, according to L. Heim (Münch. med. Woch., March 8, 1904), is methylene blue containing a sufficiently large amount of the red substance which develops with age after the addition of some alkali. The bacilli will appear blue, the capsule pink, but great care must be employed not to wash too long in water since the capsule consists chiefly of mucin and will readily dissolve out. The stain may be considered a specific reagent for mucin and will work equally well with other capsule-bacteria. Most pathogenic bacteria only possess a capsule in the animal body or if grown on blood-serum; this seems to protect them against the disintegrating powers of the blood. Occasionally the same pink substance is found in the endothelial cells of the heart and vessels of animals experimentally infected with anthrax; this is solely due to a saturation of the cells with mucin excreted by the bacteria.

Splenomegaly.—A great deal has recently been published bearing on the various forms of splenic enlargement. From the unknown Banti's disease to the well-known enlargements due to malaria and other thoroughly well understood factors, one reaches a middle ground in which the splenic enlargement is dependent upon the anomalous types of Indian fever. Presumably all of these are of plasmodium origin, but little definite is known about them. W. B. Leishman (Brit. Med. Jour., Feb. 6, 1904) states that Bently asserts that he has found the parasites described by the author in the previous communication in cases of kala-azar. Donovan has found the parasite in 16 cases, Low in two cases and Marchand has reported their occurring in a German soldier recently home from Pekin. These parasitic bodies closely resemble a form of protozoon described by J. H. Wright in the case of Delhi sore. There is no doubt in the mind of the author that they are either identical with or closely analogous to the parasitic bodies now being found in tropical splenomegaly. Wright has no doubt as to the parasitic nature of these bodies and proposes for them a new genus and species. Ross has frequently found in the pus of Delhi sores large numbers of flagellated organisms. It is possible that these may prove to be an altered form of Wright's new genus. The frequency of these sores in India and their superficial nature should facilitate the confirmation of Wright's work. Lavaran and Ross have disagreed as to the nature of these parasites. The former in his most recent publication adheres to his original view that they represent a new species of the genus *Piroplasma*. The author believes that these bodies represent an involuted stage of a flagellate organism. Certainly the failure in all cases to detect the parasites in the peripheral blood is a strong argument against their being intracorpuscular.

The Protective Function of the Greater Omentum.—It is an old idea that the greater omentum plays a protective rôle with regard to the peritoneum. R. Pirone (Arch. Ital. de Biol., Jan. 30, 1904) conducted a series of researches to determine the following questions: the details of the protective function and whether, if the blood-supply of the spleen be cut off by ligature, and if this organ be surrounded by the greater omentum, whether the latter will form a conjunctival sac around the spleen renewing its blood-supply or whether it will assist in the destruction of this organ. On practising ligature of the splenic artery on cats and rabbits, the author noticed a few days after the operation, that the greater omentum had already surrounded the spleen completely isolating it from the peritoneal cavity. The omentum shows merely a hyperemia, and in spite of the presence of a fibrinous exudation, it does not adhere to the surface of the spleen. At the end of the first week adhesion occurs, a non-detachable capsule being formed, masses of fat appearing on its surface, and the omentum of which it consists being thickened and opaque. One

week later this capsule is complete, fibrous and very adherent. The rest of the peritoneum is unchanged. There is thus observed in the case of the greater omentum, that "intelligent mobility," as it has been called, which in certain conditions serves as an efficient protective organ for the general peritoneum and the organs which it surrounds. Extirpation of the spleen is not followed by any macroscopic changes in the omentum. The author studied the histological changes occurring in the omentum encapsulating the spleen undergoing necrosis as the result of ligature of its vessels. There is from the beginning an immediate emigration of leucocytes, mostly polynuclear, which gather in the vascular spaces of the omentum, or else fill the space between the omentum and the spleen; some penetrate the capsule of the spleen. At the same time there occurs in the omentum a process which continues until the end, namely, a very active multiplication of either the vascular cells in the wall of the serous membrane or of the endothelial cells which line it. At the same time there is also a new formation of blood vessels, which little by little penetrate the capsule of the spleen. On the other hand the new endothelial cells detach themselves from the newly formed tissue, and undergoing marked intracellular changes, are transformed into macrophagocytes, which act as such. These are soon found filled with the cellular detritus of the necrosing spleen, broken-down nuclei, red corpuscles, granules of hematoidin, etc. This represents the culmination of the process which gradually subsides, and a little later (the third week in the rabbits), the necrotic tissue of the spleen has been replaced by an omental cicatrix. The omentum thus serves two functions: the plastic character of its vascular and endothelial tissues enables it not only to act the part of a scavenger in removing the dead splenic substance, but also to shield the peritoneal cavity and thereby the entire organism.

Influence of Alcohol on Resistance to Infection.—This subject has been studied by a number of observers, whose conclusions are based rather on the results of inoculations than on the actual conditions of the immunity present under the altered circumstances and do not give any information as to the manner in which the alcohol influences the specific reactionary changes in the blood. E. FRIEDBERGER (Berl. klin. Woch., March 7, 1904) in a recent investigation endeavored to find what effect the more or less continued administration of alcohol had on the production of the specific protective substances in the blood of rabbits inoculated with cholera. He found that when he gave an intoxicating dose of alcohol at the same time that the immunizing against cholera was done, the formation of the antibodies was increased on the average about 2.5 times when compared with the control animals. This seems to corroborate the clinical experience that in infectious diseases, especially in the early stages, the administration of alcohol has a decided beneficial influence on the course of the disease. It was also demonstrated that when the alcohol was given for a considerable time, the same values were reduced about 16 times as compared with the control animal. This also corresponds with the experience that during epidemics, alcoholic subjects succumb much more readily than other persons.

Distribution of Bacillus Coli in Nature.—Very little is known about this important subject. J. W. H. EYRE (Lancet, March 5, 1904) calls attention to the fact that based on the supposition that this bacillus was indigenous to the human gut, bacteriologists have long been in the habit of using it as a guide in determining the presence or absence of infection by human excreta. In order to eliminate those bacteria allied with the *Bacillus coli*, which are sometimes referred to as "coliform" and to make his report of very definite value, all bacilli not presenting the following characteristics were eliminated: Short bacillus with rounded ends; feeble motility; decolorized by gram producing acid reaction on milk; producing indol in peptone; water within three days; fermenting dextrose; lactose; maltose, saccharose mannite; glycerin; inulin; and dextrin with production of acid in gas; reducing nitrates to nitrites and forming a moist brown growth upon the potato. Despite this very close method of circumscription, the author had no difficulty in isolating large numbers of *Bacillus coli* from the intestines of the small rodents of the laboratory, also from the cat and dog. Positive results were also obtained from the sheep, goat, horse and cow. Specimens of the ordinary fowl, duck, pigeon and sparrow also yielded abundant colon bacilli. It is important that the examination should be made as soon after death as possible. Two seabirds killed three miles from land were found to harbor great quantities of these organisms. Similarly fish caught at a distance two miles from land and including many varieties all contained this germ. These findings are of very great importance in view of the modern attitude which is that the presence of *Bacillus coli communis* is pathognomonic of infection by human excrement.

Caffeine and Bacteriology.—Certain distinct uses of caffeine as an aid in bacterial diagnosis are suggested by J. COURMONT and L. LACOMME (Jour. de Physiol., March 15, 1904). Caffeine is bactericidal to many germs. The addition of this substance to the extent of one per cent. to the bouillon culture, prevents the vegetation of the colon bacillus without affecting the greater number of bacillus of Eberth. Certain bacilli of Eberth, having vegetated a long time in the laboratory, or having been recently removed from the blood of typhoid patients, are still more sensitive to the action of caffeine than the colon bacillus. The bacilli from the blood of a typhoid patient cannot vegetate in a caffeinated bouillon, while those from the urine of the same patient are not affected. This substance is mainly interesting as furnishing for the first time a bactericidal medium for the colon bacillus which will not affect certain bacilli of Eberth. It is valuable, therefore, from the standpoint of differential diagnosis. It cannot serve as a means of the diagnosis of typhoid, for the feces in the presence of the caffeinated media, presents no bacilli of Eberth.

Studies in Pneumonia and Pneumococcus Infections.—With improved technic, and using for inoculation large quantities of blood, according to E. C. ROSENOW (Jour. of Infect. Dis., March 19, 1904) the pneumococcus can be recovered in practically all cases of croupous pneumonia, and in obscure cases of pneumococcus infection blood cultures may be a diagnostic method of positive value. Pneumococcemia in pneumonia does not mean an especially unfavorable prognosis and is to be regarded here, as in subcutaneous pneumococcus infections of the rabbit, not as an especially ominous or agonal process, but rather as an integral part of the infection. There seems to be a diminution, either in the number or viability, or both, of the pneumococci in the blood at the time of crisis. The number of leucocytes in pneumonia in man and the pneumococcus infection of rabbits is an index to the degree of resistance, and the leucocytes probably constitute an important factor in combating the infection. This supports clinical observation. The hypoleucocytosis developing upon a previous hyperleucocytosis during the course of many fatal cases of pneumonia cannot be looked upon as due to the entrance of the pneumococcus cells into the blood stream, but probably as

the result of an exhaustion of the resisting powers. The leucocytosis may be incited, in part at least, by soluble substances liberated by pneumococci. It was not possible to establish any appreciable difference in the degree of virulence of the pneumococcus isolated early or late in the course of the disease, or in the fatal or non-fatal cases. Fresh normal and pneumonic blood and serum have no bactericidal influence upon the pneumococcus. Whatever other differences they may have, so far as this point goes, the serum of pneumonia patients behaves exactly as does normal serum. The interesting question whether lobar pneumonia is the primary result of a direct local infection of the lung, or a secondary localization of a primary blood invasion, is as yet hardly ripe for final discussion, but that the latter does occur, at least in some cases, is not altogether unlikely. The production of acids by pneumococci in pneumonic serum suggests that some of the toxic symptoms of pneumonia may be due to acid intoxication.

Improved Technic of Agglutination Test in Typhoid.—The method devised by Pröscher for performing this test with a twenty-four-hour bouillon culture of *Bacillus typhosus* which has been killed with formalin, has been tested by E. H. Ruediger (Jour. of Infectious Diseases, March 19, 1904) with successful results. The value of this test rests on the fact that the serum test may be applied without the use of a microscope, and merely by the use of stock cultures of typhoid bacilli killed by formalin, and a few test tubes. The technic is as follows: Inoculate a large quantity of plain bouillon (100—1,000 c.c.) with *Bacillus typhosus*, incubate at 36° C. for twenty-four hours, and add 1 c.c. formalin for every 100 c.c. of bouillon. The culture is now ready for future use, except that it must be shaken before it is used, because the dead organisms gradually settle to the bottom. A culture prepared in this manner is always ready for use, and can be kept at the room temperature for many months. With a lancet or some other sharp instrument prick the lobe of the ear or the finger tip (preferably the former) and collect four drops of blood in a small test-tube or vial containing 2 c.c. of a 1:500 solution of formalin in distilled water. Laking is soon complete, making a clear solution of approximately 1:10 to 1 c.c. of the blood solution add 4 c.c. of the dead culture, making a dilution of about 1:50, and set the tube aside. Make a control tube by mixing 1 c.c. of a 1:10 solution of normal blood, or 1 c.c. of distilled water, with 4 c.c. of the culture, and set it aside. If agglutination takes place, the dead organisms collect in clumps, and within an hour or two are seen as a flocculent precipitate settling toward the bottom, leaving the bouillon clear at the end of twelve to twenty-four hours. Dried blood may be used instead of fresh. On a glass slide collect four drops of blood, spread it and allow it to dry. When wanted for use, dissolve it in 2 c.c. of distilled water and proceed as directed above. The method is suggested as suitable for hospitals, boards of health and private practice.

Lymphatic Varices of the Small Intestine.—Frequently found in the mucosa of the digestive tract, particularly that of the jejunum, according to M. Letulle (Jour. de Physiol., March 15, 1904) is a lesion characterized by a varicosity of the lymphatics. The cause of this condition is an obstacle to the flow of lymph consisting in an obliterating endolymphitis affecting the wall of the tributary lacteal of the region affected. The coincidence of this lesion with chronic atrophic nephritis suggests a general cause capable of producing multiple or general lesions. Among the antecedents of those affected with this condition, syphilis is frequently found.

Corset Cancer.—It has long been a recognized fact that small but acute injuries are prone to develop tuberculosis while those of a similar degree, but more chronic in their infliction tend to the production of malignant change. R. Clement Lucas (Lancet, April 2, 1904) states that he has demonstrated a site of origin of cancer dependent upon the friction of the upper edge of the corset, where it crosses the anterior fold of the axilla. Whether carcinoma is produced directly by chronic irritation, or whether such irritation rubs in an organism from without is in the nature of things purely hypothetical. The rubbing in of pus-producing organisms at the back of the neck by the collar button is a well-known fact which may justly give credence to the corset theory. The author considers the possibilities of infection and contagion, attempting to show that syphilis, which produces injurious effects in numerous situations, may often be shown to be the forerunner of carcinoma. The infectiousness of carcinoma was deduced from the author's original observation of three persons suffering from carcinoma at the same time in the same house, published in 1887.

Steatogenesis in the Organs Produced Experimentally.—Very interesting results in the production of fatty changes in the various organs were obtained by C. Mavrakis (Archiv f. Anat. u. Physiol., Feb. 24, 1904). He found that removal of the thyroid gland produces a steatogenesis. Toxins (diphtheritic and typhoid) injected locally into organs whose circulation has been cut off by ligature of the arteries, produce fatty degeneration. A more intense steatogenesis is the result of repeated injections of phosphorus into organs similarly treated. The fat thus formed is produced by the metamorphosis of the cellular protoplasm, and not by the deposition of fat from other quarters. The greater part of the fat formed during fatty degeneration comes from the albumin of the cell.

Diagnosis of Empyema in Infancy.—That the physical signs of pleural effusion, especially if purulent, differ materially from those in adults, is the experience of J. L. Morse (Am. Med., March 12, 1904). He states that unless these differences are kept constantly in mind, and the diagnosis based on them rather than on unusual signs of adult life, mistakes will constantly occur. Morse sums up the question as follows: Metapneumonic empyema usually develops during the last days of a pneumonia or during the first days after the crisis, but in rare instances may develop during the early days or during the convalescence. Persistence of the fever and other symptoms after the time of the expected crisis or their recurrence after the crisis, should always suggest the possibility of an empyema. There is nothing characteristic about the symptoms, which are those of any severe pulmonary affection. Rapid emaciation and progressive pallor are the most common symptoms in neglected cases, while chills and sweating are unusual. Enlargement of the affected side as a whole is more common than flattening or bulging of the intercostal spaces. The most characteristic sign of effusion is a marked sense of resistance on the affected side. Next in importance is displacement of the heart, which almost always occurs. These two signs justify the diagnosis, even if all the other physical signs are inconsistent. Dulness or flatness is almost always present but may be replaced by tympany. Respiration is unusually bronchial or bronchovesicular and diminished in intensity. Loud bronchial respiration is not uncommon, however, even with large effusions, and counts very little if at all, against the presence of fluid. He also finds that the vocal fremitus is difficult to determine.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 14, 1904.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

The nineteenth annual meeting of the Association of American Physicians, held at Washington during the past week, the proceedings of which will be found on p. 949 of this week's Medical News, proved as ever the most interesting medical event of the year. There was the usual full attendance and that lively discussion of papers of practical import which has always characterized the meetings. The most interesting feature of the program is, that while there are no symposia announced, the discussions on the papers resolve themselves into this method of treatment, with the conventional and merely academic material left out. Special emphasis is always laid on the suggestive experiences gleaned from actual practice.

On the first day the papers on Polyuria in Typhoid Fever and the occurrence of Venous Thrombosis as a complication and sequela of that disease brought out important details with regard even to the treatment of the affection. The use of copious water drinking and its effect upon elimination of toxic material through the diuresis produced with the advisability of keeping the urine of typhoid fever patients reasonably plentiful was dwelt on. The amount of urine passed, where the patient is allowed an unlimited supply of water, may be quite surprising. With a reservoir of cool, fresh water beside the bed, connected with a tube in such a way that the patient can always take as much water and as frequently as he wishes without disturbing himself or others, gallons of water are consumed and the patient may pass as high as 400 to 500 ounces of urine. The results of such abundant flushing out of the intestinal and urinary tracts, indeed of the whole system, seems to have excellent results in the prevention of restlessness and other toxemic symptoms.

Dr. Cabot's report of negative results on blood pressure with comparatively large daily doses of strychnine, from one-eighth grain to one sixth grain, will be of interest to the many practitioners throughout the country who are accustomed to depend on strychnine as one of the most helpful of stimulants. While patients suffering from fever under such gentle emotions as those due to the visit of a friend or the coming of the dinner tray, or even some change of position, exhibited marked variations of blood pressure, which could be readily observed, no change occurred after strychnine. Dr. Hare emphasized the demonstration as to the lack of stimulant qualities of strychnine in the ordinary sense of the word. The effect of the drug is really one of irritation of the nervous system rather than any direct action upon the heart, though this is the theory on which the drug is usually employed. The most surprising feature of the discussion is Dr. Cabot's announcement that after strychnine had been administered in doses up to one-sixth grain in twenty-four hours for many days the sudden cutting off of the drug produced no effect upon the patients.

The occurrence in epidemic form of cerebrospinal meningitis in many places throughout the country makes Dr. Koplik's contribution to this subject, which will appear in full in a subsequent issue of the Medical News, of special interest. The points of differential diagnosis between this disease and tuberculous meningitis were well brought out. It is extremely important that sporadic cases secure early recognition and thus facilitate the early employment of prophylactic measures so as to prevent, as far as possible, the spread of the disease. That it is contagious there can be no doubt, though the method of distribution is unknown. The most important differential sign is the occurrence of optic papillitis, so common in tuberculous meningitis, but absent almost without exception in epidemic cerebrospinal fever.

Babinski's toe reflex is usually absent in tuberculous meningitis though commonly present in cerebrospinal. The occurrence of other cases of the disease and the suspicion of all cases showing meningitic symptoms that must be aroused in all physicians' minds at this time, will lead to the recognition of the disease.

Prof. Osler's suggestion that soldiers returning from the Philippines suffering from anemia will, in some cases at least, show the presence of the parasite described by Donovan and Leischman, which is evidently of protozoic character, should lead physicians who have such cases under their care, to look up the characteristics of the parasite. The clinical symptoms present in these cases are a decided persistent anemia accompanied by some digestive disturbances and an enlarged spleen. The affection represents doubtless another of those peculiar splenomegalic conditions which, when they develop as a result of residence in a tropical and especially malarial country, were uniformly set down as malarial in origin but which recent investigations have shown to be due to a series of pathological conditions consequent on the presence of peculiar parasites usually of protozoic nature.

The suggestion of the retiring president, Dr. Councilman, to increase the unefulness of the Association of American Physicians by making honorary members of all those who have been twenty years in the organization, which will celebrate its twentieth anniversary next year, allowing them to retain their privileges to present papers and take part in discussions but making room, even with the strict limitation of membership for younger and more active investigators, seems eminently calculated to keep for the Association the exclusiveness that has made membership a prize, at the same time secure the excellent purpose of continuous rejuvenescence. In this way the Association will retain that conservatively progressive character which has deservedly made it such a force in American life during the past score of years and will assure its own future from the inevitable tendency to sclerosis of interests that a large membership of older men might bring with it.

IMMUNITY TO RATTLESNAKE POISON.

Many years ago, when it was a novel duality for a physician to be a literary man, Oliver Wendell Holmes hinted at the possibility of immunity from rattlesnake poison in his fascinating novel "Elsie Venner." Dr. S. Weir Mitchell had published a monograph on snake poisons and Dr. Holmes' hero, who wrote his thesis on Some Unresolved Nebulæ of Medical Science, may well have taken his hint from this early study by the Philadelphian.

One of the most interesting and at the same time suggestive communications made at the recent meeting of the Association of American Physicians, was announced by Dr. S. Weir Mitchell in a letter from Dr. Noguchi, now pursuing investigations in the Institute for Serum Therapy of Copenhagen.

It may be recalled that this brilliant Japanese student was selected by the trustees of the Carnegie Research Fund to carry on special work and that following his preliminary studies with Dr. Flexner he has devoted himself more particularly to the investigation of the venom of the rattlesnake (*Crotalus*) and to the problem of the production of an immunizing serum for this venom.

In this preliminary communication, read by Dr. Mitchell, he announces his belief that he has finally obtained an efficient anticrotalic serum which promises much for human therapeutics. He writes that he has determined the minimum lethal dose of pure dried *Crotalus* venom to be .0005 mg. for 250 gms. of guinea-pig when injected intraperitoneally, and that after five months steady application he has been able to develop in the blood of the goat an anticrotalic serum which in doses of 2.5 c.c., when injected simultaneously with the snake venom, will protect the guinea-pig from twelve times the minimum lethal dose. If the antidotal serum is injected one hour after the receipt of the venom, the same amount will counteract five minimum lethal doses, and that after a period of three hours, which period he has found represents the time of maximum effect, 4 c.c. of anticrotalic serum will save the animal. Inasmuch as subcutaneous injections of venom, the analogue of the actual snake bite, are one-half as toxic as intraperitoneal applications, Noguchi views the therapeutic application of his anticrotalic serum in a distinctively hopeful light.
